Geology and Ground-Water Resources of Trego County, Kansas

ABSTRACT

Trego County is a 900-square-mile area in the High Plains section of west-central Kansas. The altitude ranges from about 2,000 to 2,600 feet above sea level. The climate is semiarid, and the mean annual rainfall is 21.40 inches. The population of the County in 1960 was 5,473. Farming and livestock raising are the chief occupations.

The Carlile Shale of late Cretaceous age is the oldest rock formation cropping out in the County. The Carlile is overlain by the Niobrara Chalk, the dominant bedrock formation in the County. The Ogallala Formation of Neogene (Pliocene) age unconformably overlies Cretaceous rocks in much of the County and consists principally of fluviatile deposits of sand, gravel, and silt. Terrace deposits of Pleistocene age occur along the principal valleys. Eolian silts that mantle the uplands and alluvium along stream valleys constitute the youngest deposits and are late Pleistocene in age.

The Ogallala Formation is the most widespread aquifer and yields water to many domestic and stock wells. Alluvium and terrace deposits yield moderate quantities of water, but these deposits are not of wide areal extent. In areas of Cretaceous outcrops, small quantities of ground water are obtained from the Dakota Formation of early(?) Cretaceous age and from the Codell Sandstone Member of the Carlile Shale of late Cretaceous age.

Hydrologic data are given in tables and include records of 280 wells, logs of 176 test holes and wells, and chemical analyses of 59 samples of water from wells.

INTRODUCTION

PURPOSE AND SCOPE OF INVESTIGATION

This report gives the results of a study of the geology and ground-water resources of Trego County, Kansas. Ground water, although often taken for granted, is one of the most vital natural resources of Kansas. The demand for water and for information concerning its availability has greatly increased in recent years because of an increasing population, accompanied by municipal, industrial, and irrigation expansion, and new water uses in the home and on the farm. The purpose of this investigation was to determine the occurrence, availability, movement, and chemical quality of ground water, and to relate the occurrence of the water to the character, thickness, and distribution of the geologic formations.

This study was made as a part of the cooperative ground-water program begun in 1937 by the State Geological Survey of Kansas and the U.S. Geological Survey, in cooperation with the Environmental Health Services of the Kansas State Department of Health and the Division of Water Resources of the Kansas State Board of Agriculture. The present status of the program is shown in Figure 1.

LOCATION AND EXTENT OF AREA

Trego County is in west-central Kansas, in the third tier of counties south of the Nebraska border and in the fourth tier of counties east of the Colorado border (Fig. 1). It is almost square, extending approximately 30 miles east-west and 30 miles north-south and has an area of about 900 square miles. It contains 25 townships, from T 11 S to T 15 S, and from R 21 W to R 25 W.

PREVIOUS INVESTIGATIONS

Cretaceous rocks of Kansas have been a subject of study since the railway explorations and the Meek and Hayden surveys of the 1860's. Adams (1898) has given an historical summary of the early studies of the Cretaceous rocks in

Kansas. Haworth contributed reports on the physiography (1897a), the physical properties of Tertiary rocks (1897b), and the geology of underground waters (1897c) in western Kansas. Logan (1897) discussed Upper Cretaceous rocks in western Kansas, and Williston (1897a) described the Niobrara Chalk and discussed the Pleistocene deposits of Kansas (1897b). Johnson (1901, 1902) discussed the Tertiary rocks of the High Plains and ground water in western Kansas. Darton (1905) discussed the geology and ground-water resources of the central Great Plains, in which he treated the loess of western Kansas as a separate formation from the underlying Tertiary deposits. In a special report on well waters in Kansas, Haworth (1913) discussed the Tertiary deposits of western Kansas and their water-bearing characteristics. Russell (1929) studied the stratigraphy and structure of the Smoky Hill Chalk Member in Logan, Gove, and Trego counties and reported on the usefulness of bentonite layers in interpreting the strati-

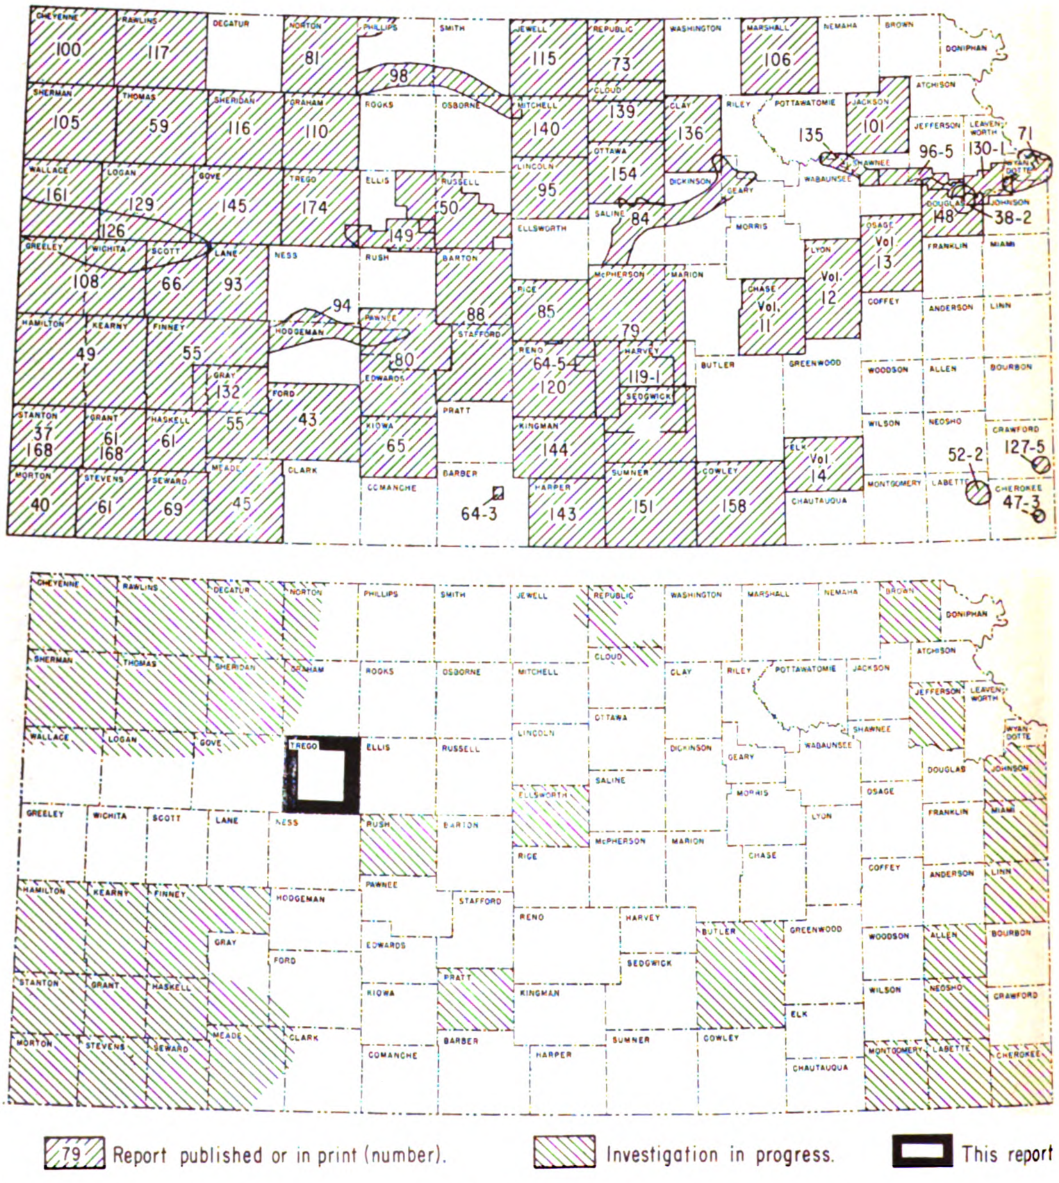

FIGURE 1.—Map of Kansas showing area discussed in this report, and other areas for which ground-water reports have been published or are in preparation.

graphy. Elias (1931) studied the geology of western Kansas with emphasis on the Pierre Shale, the Ogallala Formation, and the late Pleistocene deposits. Landes and Keroher (1939) briefly discussed the geology and petroleum resources of Logan, Gove, and Trego counties. A report by Byrne, *et al.* (1947) describes the occurrence of construction materials in the Cedar Bluff area in Trego County. Frye and Leonard (1952) discussed the Pleistocene geology of Kansas. Ground-water studies in Kansas which border Trego County, or include part of the County, were made by Prescott (1955), Hodson and Wahl (1960), and Leonard and Berry (1961). Areas in Kansas in which ground-water studies have been made, and which are published or are in preparation, are shown in Figure 1.

METHODS OF INVESTIGATION

The writer spent about three months during the summer and fall of 1959 and about three months during the summer and fall of 1960 in the field gathering data upon which this report is largely based. The areal geology was mapped from field observations and from stereoscopic study of areal photographs obtained from the U.S. Department of Agriculture. County maps prepared by the State Highway Commission of Kansas at a scale of one inch to the mile were used to record field data.

Data on 280 wells are given in Table 6 and include the depth to water and the depth of the well. Measurements were made with a steel tape graduated to hundredths of a foot. Measurements in a few wells could not be made and data on depth and water level for these wells were obtained from the owner or driller. Information concerning yield, adequacy of supply, and quality of water was obtained, if possible, from well owners. Drillers' logs of wells and test holes were obtained, if available, from well owners and well drillers.

Logs of 176 test holes and wells are given. Included are 145 sample logs of test holes, 19 logs of test holes obtained from the Bureau of Reclamation, and 4 logs obtained from the State Highway Department. Well drillers and well owners provided logs of 8 wells and test holes.

Locations of wells and test holes within the sections were determined by means of an odometer and from aerial photographs. The altitudes of measuring points of wells and test holes were determined with a plane table and alidade. The base map used for Plate 1 was compiled from maps prepared by the Soil Conservation Service, U.S. Department of Agriculture.

Samples of water from representative wells were collected and were analyzed by Howard A. Stoltenberg, Chief Chemist, in the Sanitary Engineering Laboratory of the Kansas State Department of Health.

WELL-NUMBERING SYSTEM

The locations of wells, test holes, and local features are designated in this report according to General Land Office surveys in the following order: township, range, section, quarter section, quarter-quarter section, and quarter-quarter-quarter section (10-acre tract). The quarter sections, quarter-quarter sections, and 10-acre tracts are designated *a*, *b*, *c*, or *d* in a counterclockwise direction beginning in the northeast quarter section. For example, well 11-24-25acb is in the NW SW NE sec. 25, T 11 S, R 24 W (Fig. 2). If more than one well or test hole is located in the same 10-acre tract, the location numbers are followed by serial numbers in the order in which they were inventoried.

ACKNOWLEDGMENTS

Thanks and appreciation are expressed to the many residents who gave permission to inventory their wells and who allowed access to their property for the study of rock exposures, to those who permitted aquifer tests to be made using their wells, and to the municipal officials who provided data concerning city water sup-

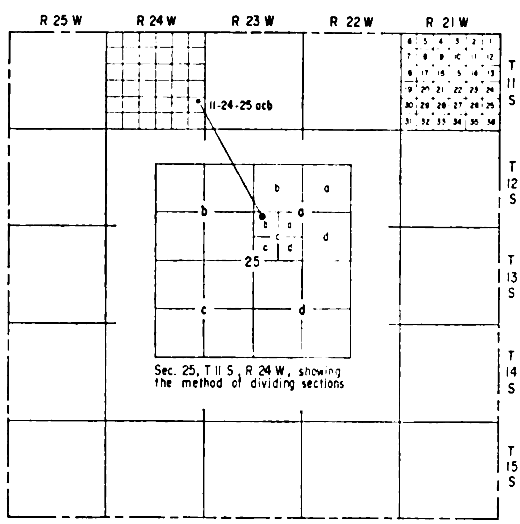

FIGURE 2.—Map of Trego County, Kansas, illustrating the well-numbering system used in this report.

plies. The Trego County office of the Soil Conservation Service, U.S. Department of Agriculture, located at WaKeeney, gave helpful information.

E. L. and Carrie Reavis and Melvin Franz, of the U.S. Geological Survey and the State Geological Survey of Kansas, gave assistance during field work. The illustrations were drafted by Judy Crissler and Larry Shelton.

The manuscript for this report has been reviewed by members of the U.S. Geological Survey and the State Geological Survey of Kansas; by Robert V. Smrha, Chief Engineer and Harris L. Mackey, Engineer, of the Division of Water Resources of the Kansas State Board of Agriculture; and by J. Lee Mayes, Chief Engineer, and Bruce F. Latta, Geologist, of the Environmental Health Services of the Kansas State Department of Health.

GEOGRAPHY

TOPOGRAPHY AND DRAINAGE

Most of Trego County lies within the High Plains section of the Great Plains physiographic province (Fig. 3) as designated by Schoewe (1949, p. 276). The southeastern corner of the County is in the Blue Hills division of the Dissected High Plains section. Gently rolling uplands that are moderately dissected by smaller drainageways characterize much of the County. Near the major streams, the slopes are quite steep and the topography is rough. Slopes along the north sides of the valleys of the larger streams are relatively more gentle and longer than along the south sides, whereas slopes along the southern sides tend to be cut into steep canyons and badlands. The Fort Hays Limestone Member of the Niobrara Chalk forms prominent escarpments in the southeastern part of the County and along the Smoky Hill Valley. One of the more prominent physiographic features along the Smoky Hill Valley is a high terrace. The surface of the terrace is about 50 feet above the level of the flood plain and about 200 feet below the general level of the upland. Loess and slope wash obscure the outer margin of the terrace in most places.

Three perennial streams cross the County, all flowing in an easterly direction, and are part of the Kansas River drainage system. The Smoky Hill River flows across the southern part of the County, Big Creek across the central part, and the Saline River along the northern edge of the County.

Pediment slopes are characteristic of the outer valleys of the major streams. Along the Smoky Hill River valley, long pediment slopes mask the prominence of the Fort Hays escarpment and grade into the high terrace. Along the Saline River Valley, the pediments are developed on the soft Cretaceous chalk beds and blend into

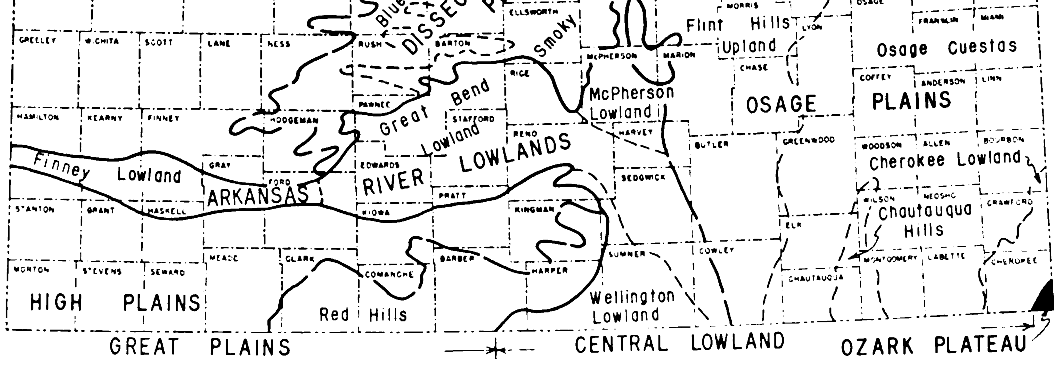

FIGURE 3.—Map of Kansas showing physiographic regions. (From Schoewe, 1949, fig. 22.)

the terrace surface so imperceptibly that the upland edge of the terrace cannot be mapped precisely without subsurface information.

The general slope of the land surface in Trego County is eastward. The total topographic relief is about 600 feet. The lowest elevation, about 2,000 feet above sea level, is in the channel of the Smoky Hill River on the eastern county line in the NE sec. 1, T 15 S, R 21 W. The highest elevations are in the uplands in the west-central and northwestern parts of the County and are about 2,600 feet above sea level.

CLIMATE

Trego County has a semiarid continental climate. Low to moderate precipitation, a high rate of evaporation, reasonably mild winters, and fairly hot summers are typical. The hot weather in summer is moderated by brisk winds and low humidity. As a rule the winters are moderate with only short periods of severe cold weather and relatively little snowfall. A large percentage of the winter days are clear, but snow flurries are common, and occasionally the area is subjected to blizzard conditions. In Trego County, the amount of precipitation and its seasonal distribution are the controlling factors in crop growth. Rainfall is erratic, coming sometimes as storms of 4 inches or more, and at other times, in no appreciable amount for several weeks.

The climatic data in this report were compiled from published records of the U.S. Weather Bureau (U.S. Department of Commerce). Approximately 70 percent of the annual precipitation in Trego County falls during the growing season of about 5½ months (Fig. 4). The mean annual precipitation at WaKeeney is 21.40 inches (based on period of record 1931-55). The greatest annual precipitation recorded was 37.37 inches in 1961; the least was 11.15 inches in 1888. The annual precipitation for the period of record and the cumulative departure from normal precipitation are shown in Figure 5. The average length of the growing season is 167 days, the average date of the last killing frost in spring being April 27, and the average date of the first killing frost in fall being October 11.

POPULATION

According to the U.S. Census Bureau, Trego County had a population of 5,473 in 1960, of which approximately 50 percent was urban and 50 percent rural. The County had an average of

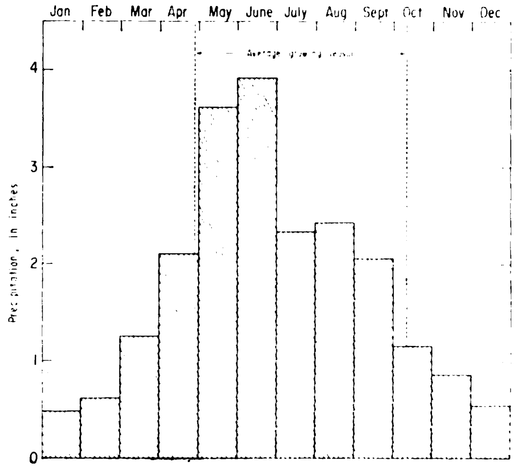

FIGURE 4.—Normal monthly precipitation at WaKeeney (1931-1955) and average growing season.

6.1 persons per square mile as compared to a State average of 26.6 persons. WaKeeney, the county seat, had a population of 2,808. Other communities are Collyer, population 233, and Ogallah, unincorporated.

GENERAL GEOLOGY

SUMMARY OF STRATIGRAPHY[1]

The rocks that crop out in Trego County are sedimentary in origin and range in age from Cretaceous to Recent. Their areal distribution is shown on Plate 1; their stratigraphic relation is illustrated by cross sections on Plate 2 and in Figure 6. A generalized section of the rock units and their water-bearing properties are given in Table 1.

The Carlile Shale of late Cretaceous age is the oldest geologic formation exposed in Trego County. The Carlile crops out along the Smoky Hill Valley east of the junction of the Smoky Hill River and Hackberry Creek and is buried beneath rocks of younger age in the rest of the County.

The Niobrara Chalk of late Cretaceous age overlies the Carlile Shale. The Niobrara crops out along the outer valleys of the Smoky Hill and Saline rivers and their tributaries and along Big Creek valley in the eastern part of the County. The Niobrara Chalk is divided into two members, the Fort Hays Limestone below and the Smoky Hill Chalk above.

[1] The classification and nomenclature of rock units described in this report follow that of the State Geological Survey of Kansas and differ somewhat from the classification and nomenclature of the U.S. Geological Survey.

The Ogallala Formation of Neogene age (Pliocene) unconformably overlies the Cretaceous rocks in much of the upland areas of the County. Erosion during the Pleistocene Epoch has removed the Ogallala along the Saline and Smoky Hill valleys and in the eastern part of the County along Big Creek valley. Along the Smoky Hill Valley, the Ogallala has been removed along a belt as much as two townships wide, exposing Cretaceous chalk and shale.

Unconsolidated deposits of both fluviatile and eolian origin represent the Pleistocene Series. Fluviatile deposits fill channels cut into Cretaceous bedrock along the principal streams. Eolian deposits mantle the uplands and in many places overlie older terrace deposits along stream valleys. Deposits belonging to the Pleistocene Series are the Grand Island and Sappa formations of Kansan age, the Crete and Loveland formations of Illinoisan age, the Peoria Formation of Wisconsinan age, and alluvium of Wisconsinan and Recent age.

In this report the Grand Island, Sappa, and Crete formations are shown in the illustrations and discussed as terrace deposits, and the Peoria and Loveland formations are discussed together

TABLE 1.—Geologic formations in Trego County, Kansas, and their water-bearing properties.

System	Series	Stratigraphic unit	Maximum thickness, feet	Physical character	Water supply
Neogene	Pleistocene	Alluvium (incl. Recent and late Wisconsinan terrace deposits)	70	Stream-deposited silt, sand, and gravel; thick, coarse deposits in major valleys, finer deposits in smaller valleys	Yields moderate to large quantities of water to wells along major valleys; lesser amounts along smaller valleys
		Peoria and Loveland formations	30	Silt, mostly eolian, sandy in lower part. Mantles most of uplands and masks much of valley walls	Yields small amounts of water to wells locally
		Grand Island, Sappa, and Crete formations (Terrace deposits)	100	Stream-deposited sand, gravel, and silt in a terrace position along major valleys. Locally contains Pearlette ash bed	Yields small to moderate quantities of water to wells along major valleys
	Pliocene	Ogallala Formation	150	Fluviatile deposits of sand, gravel, silt, and clay; mostly unconsolidated, but cemented at places to various degrees	Yields moderate quantities of water to wells in much of the County
Cretaceous	Upper Cretaceous	Niobrara Chalk: Smoky Hill Chalk Member	500	Chalk and chalky shale, thin-bedded and platy; bentonite beds throughout. Light gray to dark gray when fresh; weathers to brown and orange at outcrop	Yields no water to wells
		Niobrara Chalk: Fort Hays Limestone Member	55	Massive chalk beds separated by thin chalky shale partings, grayish-white, but may be yellow or light brown at outcrop	Yields small amounts of water to wells locally
		Carlile Shale	300	Lower part consists of gray calcareous shale and thin beds of chalky limestone; upper part consists of dark-gray clayey shale with silty fine-grained sandstone lenses in upper part	Yields small amounts of water to wells from Codell Sandstone Member
		Greenhorn Limestone	100	Alternating beds of chalky limestone and chalky shale	Yields no water to wells
		Graneros Shale	45	Noncalcareous dark-gray shale; persistent bentonite bed in upper part	Do
	Lower(?) Cretaceous	Dakota Formation	300	Clay, shale, siltstone, and sandstone; interbedded and varicolored. Sandstone fine- to medium-grained and lenticular. Lignite and "ironstone" common	Yields small amounts of water to wells

as loess deposits. Figure 6 illustrates the stratigraphic relation of Pleistocene deposits across the principal valleys. Deposits penetrated in test holes 13-21-5bbc and 13-21-8abb, along the north side of Big Creek valley, may be of Nebraskan age.

UNEXPOSED ROCKS

Geologic rock units below the Carlile Shale that do not crop out in Trego County but occur in the subsurface within a possible drilling depth for water wells consist of approximately 500 feet of Greenhorn Limestone, Graneros Shale, and Dakota Formation. The Greenhorn Limestone and Graneros Shale are not considered to be aquifers. The Dakota Formation is an important source of ground water for domestic and stock purposes in parts of Trego County. These formations will be discussed further in the section on geologic formations and their water-bearing properties.

ECONOMIC GEOLOGY

GROUND WATER

Source

Figure 7 is a diagram of the hydrologic cycle adapted from Piper (1953) showing the part of ground water in the circulation of water near the surface of the earth. The earth's water is constantly circulating from air to ground to air in a process called the hydrologic cycle. Water falls to the ground in the form of precipitation such as rain, snow, sleet, or hail. Part of this water vaporizes and returns to the air by evaporation, a part is removed as runoff via rivers to the ocean, a part percolates into the ground by infiltration, some of which is used by trees and vegetation and is returned to the air through a process called transpiration, and a very small part percolates downward through the soil and underlying strata until it reaches the water table, where it becomes ground water. The hydrologic cycle of rainfall, evaporation, runoff, infiltration and transpiration is continuous. It is this cycle which provides the source of our ground water. Figure 8 shows the generalized divisions of subsurface water.

Where a water-bearing formation is confined between relatively impermeable beds and water is supplied to it from an adjacent area of higher altitude, the water table is absent and the water is said to be confined or under artesian pressure. When an aquifer under artesian pressure is penetrated by a well, water will rise in the well to a height equal to the hydraulic head. The imaginary surface connecting this level in wells

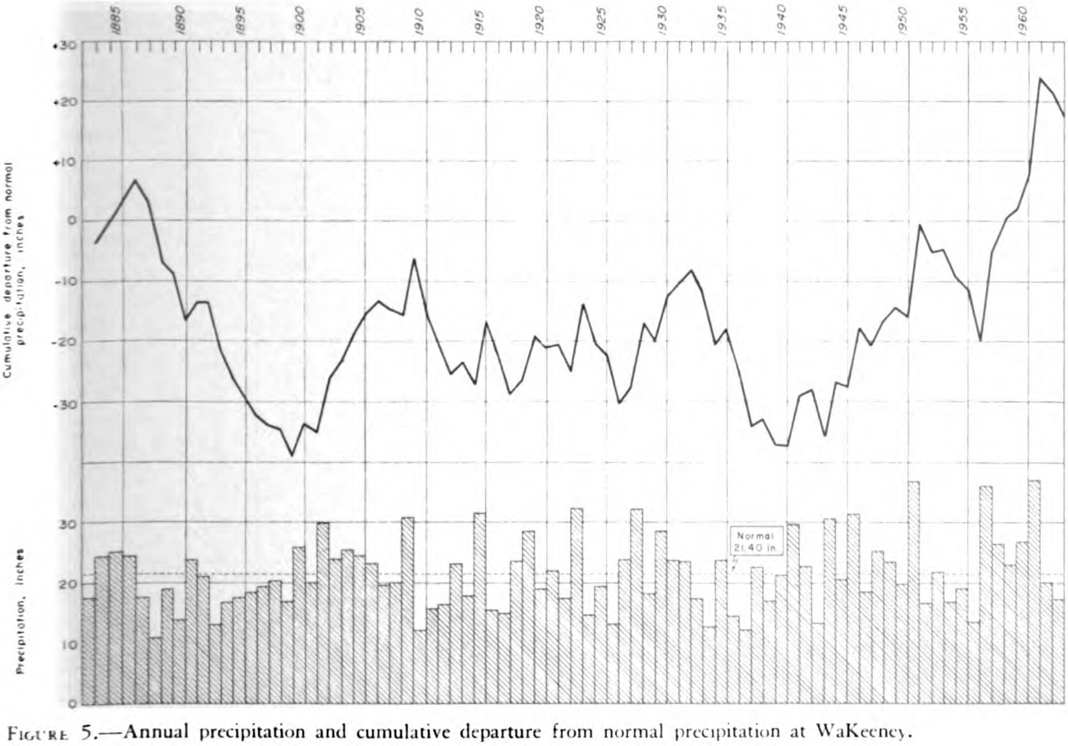

Figure 5.—Annual precipitation and cumulative departure from normal precipitation at WaKeeney.

is called the *piezometric surface*, which may or may not be above the land surface. Ground water in the Dakota Formation in Trego County is under artesian pressure, the water rising in some wells as much as 300 to 400 feet above the top of the Dakota. Water in the Codell Sandstone Member rises nearly 200 feet above the top of the Codell in some of the deeper wells in the County. Ground water in the Dakota and in the Codell is discussed further in the section on geologic formations and their water-bearing properties.

The Water Table and Movement of Ground Water

The water table fluctuates up and down in response to additions to or withdrawals from an aquifer. Fluctuations of the water table can be determined by periodic measurements of the depth to water in wells. The depth to water has been measured periodically since 1949 in several wells in the Smoky Hill Valley below the Cedar Bluff dam. These measurements have been published annually by the U.S. Geological Survey (1936-1959) and thereafter by the State Geologi-

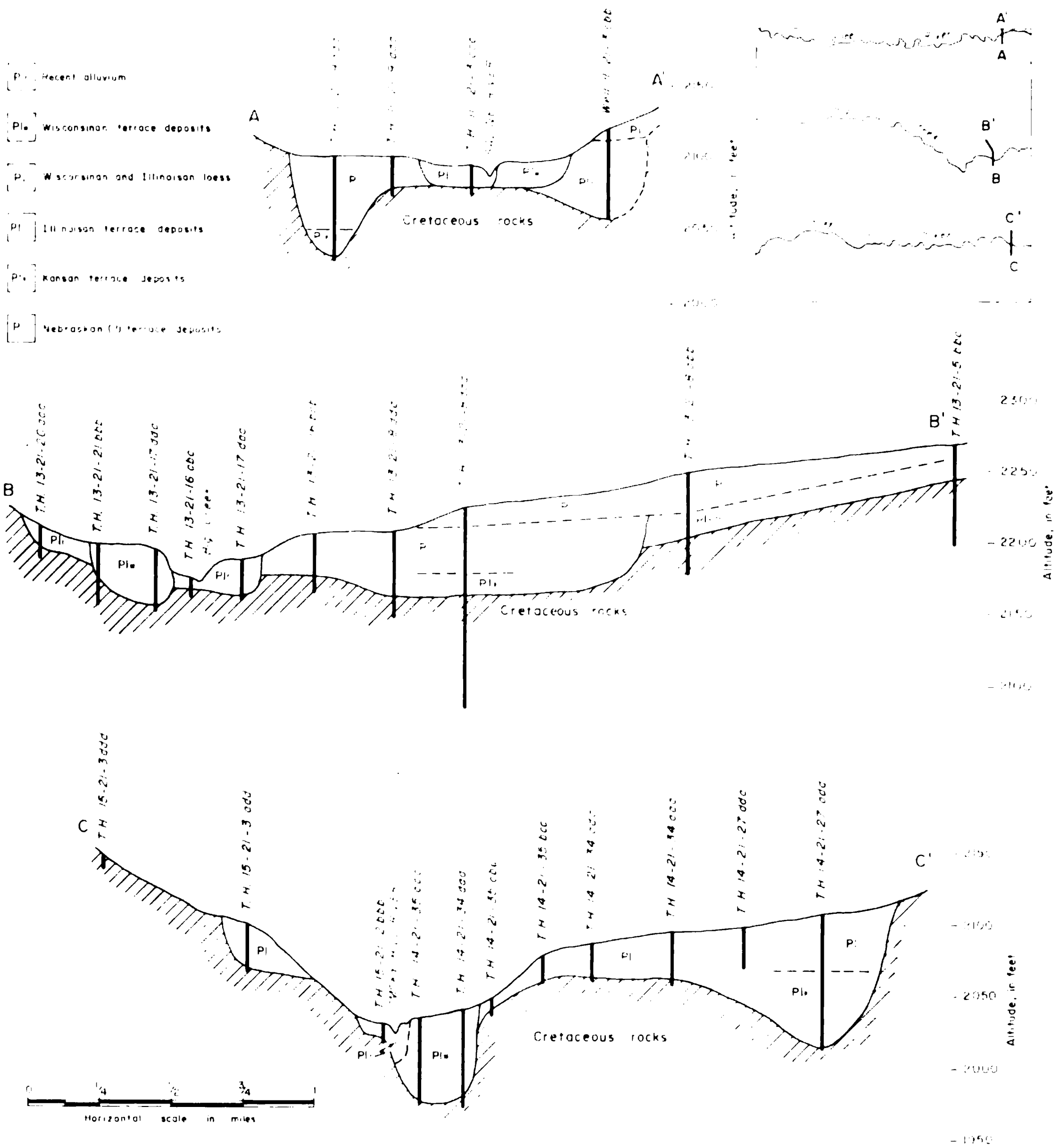

Figure 6.—Stratigraphic relation of Pleistocene deposits across Saline River (A-A'), Big Creek (B-B'), and Smoky Hill River (C-C') valleys.

cal Survey of Kansas (1958-1963). Hydrographs in Figure 9 show fluctuations of ground-water levels below the Cedar Bluff dam. The hydrograph of well 14-22-36aab, about a mile below the dam, reflects seepage from the reservoir which was filled in 1951.

The configuration of the water table in the Ogallala Formation in the northern part of the County is shown on Plate 1 by means of contour lines. The direction of ground-water movement is at right angles to the contours and in a downslope direction. The movement is generally eastward, but along the outer edges of the upland the contours bend back reflecting discharge along the edge of the upland. Local anomalies in the water-table contours along the edge of the upland indicate areas of greater recharge due to the predominance of sand and gravel near the land surface where the upland loess has been removed by erosion, exposing the coarser clastic deposits of the Ogallala.

Ground water in the alluvial valleys of the Smoky Hill and Saline rivers is not continuous with ground water in the Ogallala Formation in the uplands but is separated from it by impermeable Cretaceous rocks. Along Big Creek in the central and western parts of the County, however, the water table is continuous with the water table in the Ogallala, and water-table contours show that ground water from the Ogallala is discharging into terrace deposits and alluvium and from there into Big Creek (Pl. 1).

No long-term record of observation wells in the Ogallala Formation in Trego County is available. At the present rate of withdrawal, the water level is fairly stable and ground-water recharge and movement into the County is in equilibrium with discharge and movement from it.

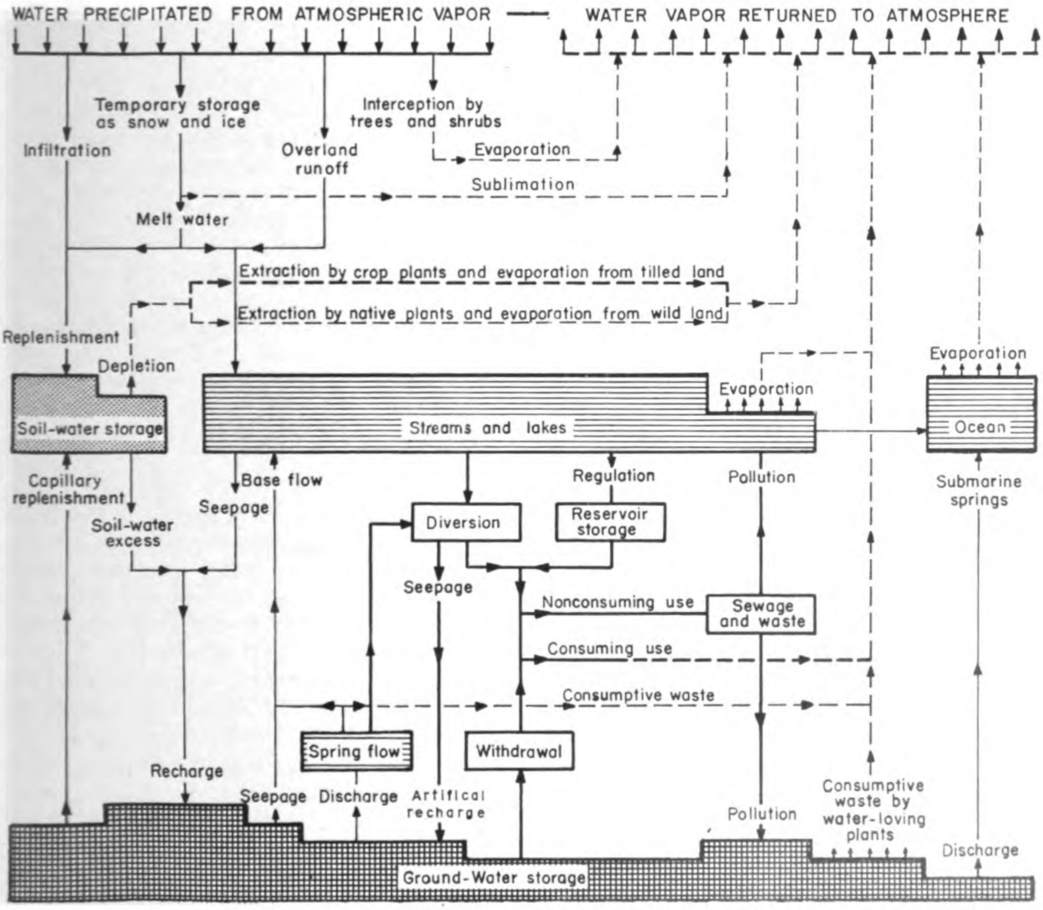

FIGURE 7.—Diagram of the hydrologic cycle. Solid flow lines indicate movement of water as a liquid and broken lines movement as vapor. Heavy flow lines indicate man's principal interruption of the natural cycle (after Piper, 1953).

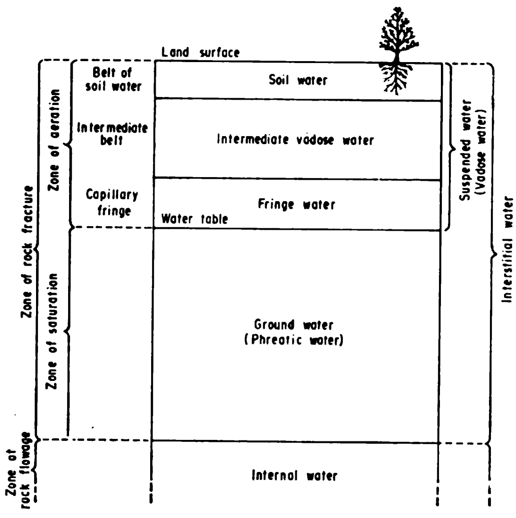

FIGURE 8.—Diagram showing generalized divisions of subsurface water (after Meinzer, 1923, fig. 2).

ADDITIONS OF GROUND WATER

Additions to the ground-water reservoir may occur in several ways: by direct infiltration of precipitation, by seepage of water from streams, by subsurface inflow of water from adjacent areas, and by infiltration of irrigation water applied to the land.

INFILTRATION OF PRECIPITATION

Approximately 60 percent of the mean annual precipitation in Trego County falls during the months of May through August when the climate is characterized by brisk wind movement, high temperatures, and relatively low humidity. Consequently, evaporation is rapid, and much of the precipitation is returned to the atmosphere. Because much of the rainfall occurs during the growing season, a considerable part of the precipitation is returned to the atmosphere through transpiration of plants.

The topography, vegetative cover, and nature of the subsoil greatly affect the amount of water that will infiltrate below the land surface. The upland areas underlain by the Ogallala Formation are conducive to infiltration of rainfall in areas where sand and gravel crop out. Where thick loess deposits cover the Ogallala, infiltration is retarded.

The alluvium and terrace deposits along stream valleys are very conducive to infiltration because of the sandy nature of the deposits, the low relief, and the shallow depth to water. These deposits, however, are of relatively small areal extent. The annual quantity of recharge by infiltration of precipitation in Trego County is not known, but it is believed to be a small percentage of the total precipitation that falls in the County. Nevertheless, this recharge probably amounts to at least 10,000 acre-feet per year.

INFLUENT SEEPAGE FROM STREAMS

Smoky Hill River, Saline River, and Big Creek are effluent streams in Trego County. Their channels are cut below the water table and thus generally are receiving water from, rather than adding water to, the zone of saturation (Fig. 10). Deposits adjacent to the channels are recharged during flood stages, but the water represents temporary "bank" storage and returns to the stream soon after the flood. Smaller tributaries in the County lie above the water table and during periods of stream flow, contribute water to the underlying strata where the channel is underlain by deposits that are conducive to infiltration.

SUBSURFACE INFLOW

The quantity of subsurface inflow to the County is not known, but it is estimated that from 3 to 4 acre-feet of ground water per day moves into Trego County from the west through the Ogallala Formation (1 acre-foot equals 325,850 gallons). A small amount of ground water enters the County along the northern boundary, chiefly in valleys tributary to the Saline River valley. Some ground water also enters the County by movement in alluvium and terrace deposits along the major stream valleys. Because of the small cross-sectional area of the valley deposits, the amount of ground-water movement in them is relatively small.

INFILTRATION OF IRRIGATION WATER

Recharge from water applied to the land for irrigation has been estimated to approach 25 percent of the applied water in certain irrigated areas. In these areas, the irrigated water is distributed in relatively long ditches over soils and subsoils that are very permeable.

Irrigation in Trego County is confined chiefly to the Big Creek and Saline River valleys where the soils are sandy loam. The percentage of applied water that recharges the alluvium of these valleys is not known but probably is considerable in small local areas. Because irrigation is not practiced extensively and because the areal extent of the alluvial valleys is relatively small, the amount of recharge to the aquifer from infiltration of irrigation water is not significant.

In Trego County, much of the upland plain is thickly mantled by loess and has a relatively dense soil, and recharge probably does not exceed an average of 10 percent of the applied irrigation water. Because only a few irrigation wells obtain water from the Ogallala in Trego County, the amount of recharge to the aquifer from infiltration of irrigation water is considered to be negligible.

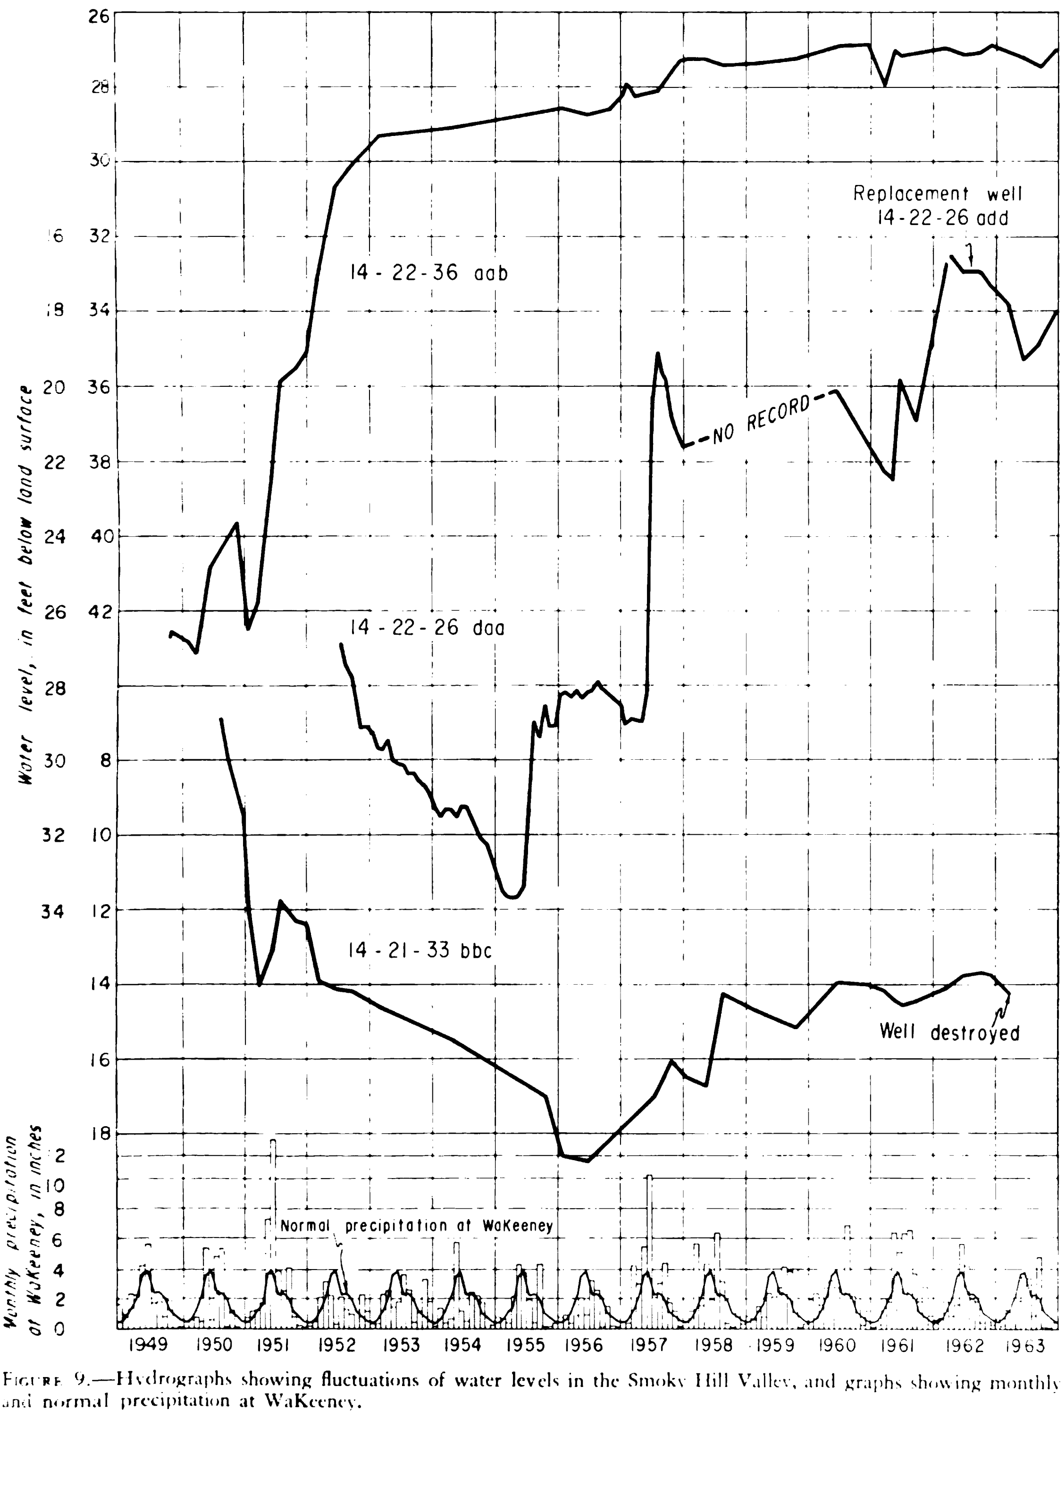

FIGURE 9.—Hydrographs showing fluctuations of water levels in the Smoky Hill Valley, and graphs showing monthly and normal precipitation at WaKeeney.

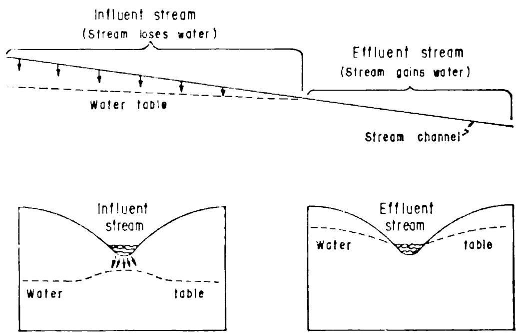

FIGURE 10.—Diagrammatic sections showing influent and effluent streams. *A*, Longitudinal section showing how a stream gains water (right) and how it loses water (left). *B*, Transverse section across influent part of a stream. *C*, Transverse section across effluent part of a stream. (After Meinzer, 1923, fig. 26).

Ground-Water Discharge

Subtractions from the ground-water reservoir in Trego County include discharge by effluent seepage into streams, discharge of springs, transpiration and evaporation, discharge from wells, and subsurface outflow.

SEEPS AND SPRINGS

Streamflow is maintained at low stages along the perennial streams in the County by ground-water discharge into the streams, mainly as seeps along stream channels. Discharge is chiefly from alluvial and terrace deposits, but along Big Creek, in the western and central parts of the County, the Ogallala Formation is in contact with the valley deposits and discharge occurs from the Ogallala into the valley deposits. Small springs occur at places where the contact of the Ogallala Formation and underlying Cretaceous rocks crop out. Springs also occur along the edges of the high terrace deposits in the Smoky Hill Valley. The amount of discharge of ground water by springs and seeps in Trego County is not known, but it is believed to be considerable.

TRANSPIRATION AND EVAPORATION

Shallow ground water along the major streams supports a heavy growth of vegetation, and during the growing season a significant amount of ground water is transpired by these plants. The quantity of ground water discharged in this manner is difficult to determine, but it probably exceeds the discharge by all other means combined. Transpiration reduces the ground-water discharge into a number of streams, and flow in these streams during the growing season is largely runoff from storms.

After the first killing frost in the fall, perennial streams show an appreciable increase in flow due to a decrease in plant transpiration. In the upland areas transpiration does not occur from the water table because of the greater depth of the water table. Soil moisture lost by transpiration on the uplands, however, must be replaced before any water can infiltrate downward to the water table.

Where the water table is within a few feet of the land surface, ground water may evaporate from the capillary fringe overlying the zone of saturation, or, if the water table is within a few inches of the land surface, water may evaporate directly from the zone of saturation. The evaporation of water from the ground-water reservoir in the County is restricted to the alluvial valleys and the amount is probably small compared to other means of ground-water discharge.

PHREATOPHYTES

Phreatophytes are plants that characteristically grow where they can send their roots down to the water table, or to the capillary fringe, and thus obtain their water supply. Most phreatophytes are of low economic value, and the water they transpire to the atmosphere is defined as "consumptive waste." More than 70 plant species have been classified as phreatophytes (Robinson, 1958, p. 1), some of the more common being pickleweed, rabbitbrush, salt grass, alfalfa, cottonwood, willow, greasewood, and salt cedar. Salt cedar *(Tamarix pentandra)* is a serious problem in many stream valleys in the southwestern and western United States. In places, salt cedar has developed a jungle-like growth, invading and choking overflow channels of streams, and producing serious flood hazards. The eradication or control of salt cedar is very difficult and expensive. The annual use of water by salt cedar in areas of heavy growth may be several acre-feet per acre.

Salt cedar has invaded some stream valleys in Kansas and is now found along the Cimarron and Arkansas valleys in southwestern Kansas, Smoky Hill and Saline valleys in west-central Kansas, and South Fork and North Fork Solomon valleys in north-central Kansas (Tomanek and Ziegler, 1963).

Salt cedar has been used extensively as a shelter belt in Trego County and is also found as an ornamental shrub in many farm yards in the County. A number of places around the Cedar Bluff reservoir have become heavily infested with salt cedar. Ecological studies of salt cedar in the Cedar Bluff area (Tomanek and Ziegler, 1963) show that the plant benefits from a drought or conditions that keep the water level falling or low for a long period of time.

DISCHARGE FROM WELLS

Ground water is pumped for municipal, domestic, stock, and irrigation use in Trego County. Municipal water departments in the County reported a total use of about 450 acre-feet of ground water in 1960. Records of the Division of Water Resources of the Kansas State Board of Agriculture show that 3,487 acre-feet of ground water per year were appropriated for irrigation in the County as of April, 1963. The amount of ground water reported as used for irrigation in 1962 was 333 acre-feet. This amount may vary considerably, depending upon rainfall. Most rural residents obtain water for domestic and livestock use from small-diameter drilled wells equipped with cylinder pumps powered by windmills. The yields of these wells are small and probably average about one gallon a minute. Because of their great number and long pumping periods, however, such wells represent an important withdrawal of ground water, estimated to be about 800 acre-feet per year for both household and stock purposes. Withdrawal of ground water from wells is increasing somewhat because of new water uses in the home and on the farm. There is also a small annual increase in the number of irrigation wells in the County, mostly in the alluvial valleys.

SUBSURFACE OUTFLOW

Ground-water contours on Plate 1 show the subsurface flow of ground water to be in a generally eastward direction in the northern part of the County. In most areas the contours bend westward along the edge of the uplands, indicating discharge from the uplands toward the stream valleys. The amount of outflow in the alluvial valleys is small because of the relatively small cross-sectional area of the alluvial valleys. It is estimated that about 700 acre-feet of ground water per year leaves Trego County by subsurface outflow.

Hydrologic Properties of Water-Bearing Materials

The quantity of ground water that an aquifer will yield to wells depends upon the hydrologic properties of the material forming the aquifer. The hydrologic properties of greatest significance are the ability to transmit and to store water, which are measured by the coefficients of transmissibility and storage. Controlled aquifer tests in the field provide the data required to compute these coefficients.

The coefficient of transmissibility (T) may be expressed as the rate of flow of water, in gallons per day, through a vertical strip 1 foot wide and extending the full height of the saturated thickness of the aquifer, under a hydraulic gradient of 1 foot per foot, at the prevailing ground-water temperature.

The coefficient of storage (S) may be expressed as the change in the stored volume of water per unit surface area of the aquifer per unit change in the component of head normal to that surface.

The field coefficient of permeability (P) may be expressed as the rate of flow of water, in gallons per day, through a cross-sectional area of 1 square foot, under a hydraulic gradient of 1 foot per foot, at the prevailing ground-water temperature. The field coefficient of permeability can be computed by dividing the coefficient of transmissibility by the aquifer thickness (m).

DETERMINATIONS OF TRANSMISSIBILITY AND PERMEABILITY

Aquifer tests were made using two irrigation wells, 12-23-20ccc, deriving water from alluvium in Big Creek valley, and 12-23-30acc, deriving water from terrace deposits along Big Creek valley. Details of the wells are given in the table of well records at the end of this report. Observation wells for drawdown measurements were constructed at appropriate distances from the pumped wells. Figures 11, 12, 13, and 14 give the results of these tests. Values of transmissibility were computed from the test data by the methods generally referred to as the Thiem formula, the Theis nonequilibrium formula, the Jacob modified nonequilibrium formula, and the Theis recovery formula. The theory of these formulas and their application are discussed by Ferris, *et al.* (1962).

The aquifer tests indicate that a coefficient of transmissibility of about 40,000 gpd per foot may be expected in the alluvium at localities where the saturated thickness is adequate and where reasonably good sand and gravel beds are in the saturated zone. Test drilling should disclose the more favorable well sites.

Although the aquifer test in the terrace deposits shows a coefficient of transmissibility of about 120,000 gpd per foot, the transmissibility is too high for most deposits shown as terrace deposits in this report. Deposits in the vicinity of well 12-23-30acc are thicker, better sorted, and have a greater saturated thickness than is characteristic of terrace deposits in most of the County. Also, in this area along the central and western reaches of Big Creek, terrace deposits are adjacent to, and in many places lithologically indistinguishable from, the Ogallala Formation. The water table in the terrace deposits is continuous with the water table in the Ogallala Formation and ground water moves from the Ogallala Formation into the terrace deposits. When pumping occurs in the terrace deposits, there is increased movement of ground water from the Ogallala into the terrace deposits toward the area of drawdown. In contrast, along the Saline River and Smoky Hill River valleys and along Big Creek valley in the eastern part of the County, the terrace deposits are separated from the Ogallala by wide areas of impermeable Cretaceous shale.

The coefficients of storage calculated in aquifer test 12-23-30acc (Fig. 13) show a change from artesian to water-table conditions as pumping continued. Logs of test holes in the alluvium and terrace deposits show that silt and clayey silt are characteristic of the upper part of the deposits and that sand and gravel generally occur in the lower part. The silt beds cause a slight artesian effect because of confinement of ground water below these less permeable silt beds.

Utilization of Ground Water

Data on 280 wells in Trego County are given in Table 6. Only part of the domestic and stock wells were visited, but records were made of all municipal and irrigation wells in the County at the time of this investigation. The principal uses of ground water in the County are listed below.

Domestic and Stock Supplies

One of the chief uses of ground water in Trego County is to supply domestic and stock needs. Nearly all domestic and stock supplies in the rural part of Trego County are obtained

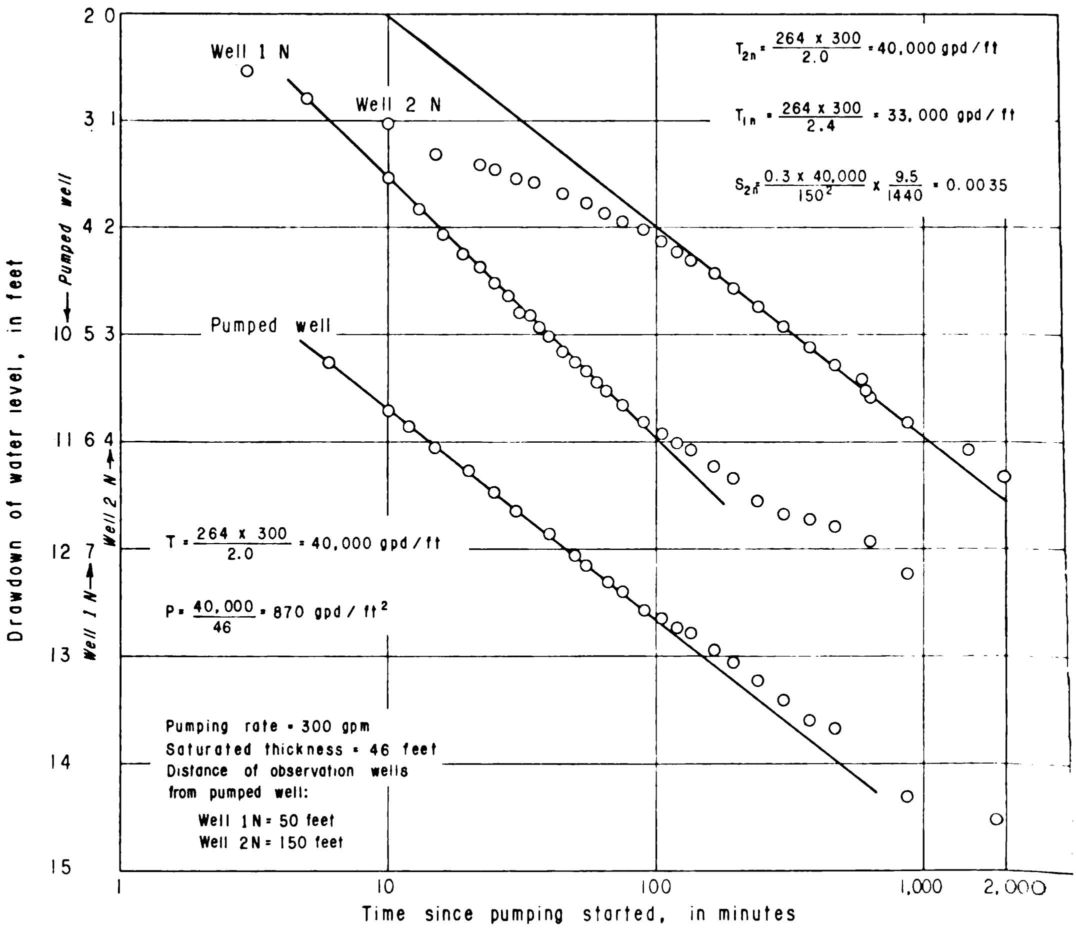

Figure 11.—Drawdown of water levels in pumped well and observation wells during aquifer test, plotted against time since pumping started (well 12-23-20ccc).

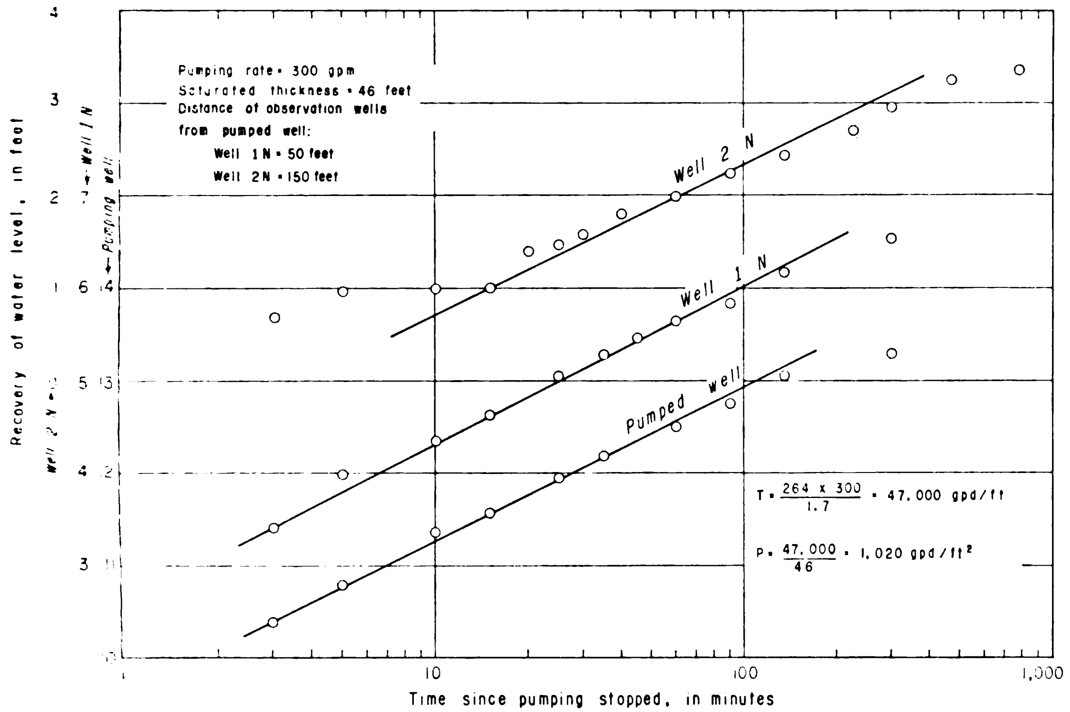

FIGURE 12.—Recovery of water levels in pumped well and observation wells during aquifer test, plotted against time since pumping stopped (well 12-23-20ccc).

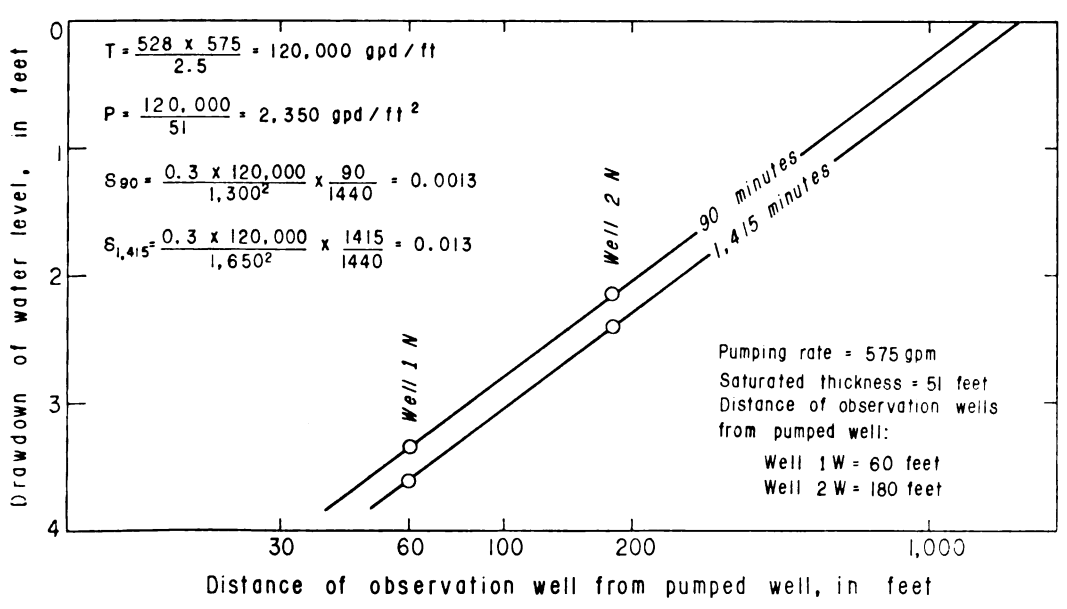

FIGURE 13.—Drawdown of water levels in observation wells during aquifer test at 90 and 1,415 minutes after pumping started, plotted against distance from pumped well (12-23-20ccc).

from wells, but in parts of the County where ground water is difficult to obtain, some stock supplies are provided by dams constructed across small watercourses. Most domestic and stock wells in the County are drilled wells in which casing has been set and which are equipped with displacement-type pumps in which the cylinder is below the water level. Most pumps are operated by windmills; the others are operated by electric or gasoline motors, or by hand.

MUNICIPAL SUPPLIES

At the time of this investigation only the communities of WaKeeney and Collyer maintained municipal water-supply systems. Data regarding individual wells and details of well construction are given in Table 6.

WaKeeney.—The city of WaKeeney obtains its water supply from seven drilled wells in the alluvial deposits of Big Creek valley about 2 miles south of the city. The wells are equipped with electrically driven turbine pumps; yields range from about 100 to 500 gpm. A reserve well is also maintained at the east edge of town which derives water from the Ogallala Formation. Storage is provided by 2 elevated storage tanks with capacities of 250,000 and 75,000 gallons and 2 underground reservoirs with capacities of 200,000 and 100,000 gallons. Water used in 1960 was about 136 million gallons, as reported by the WaKeeney Water Department.

Collyer.—The city of Collyer obtains its water supply from two drilled wells in the Ogallala Formation at the southwest edge of the city. The wells are equipped with electrically driven turbine pumps; yields are about 100 gpm. Storage is provided by an elevated 55,000-gallon tank. An annual use of about 10 million gallons was reported by the Collyer Water Department.

IRRIGATION SUPPLIES

There were 22 irrigation plants in Trego County by the fall of 1960, most of which were in the alluvial valleys. Nearly all were single wells, but a few plants were pumping from batteries of two or more wells. Yields of the irrigation wells ranged from about 150 gpm to about 1,000 gpm. According to records of the Division of Water Resources of the Kansas State Board of Agriculture, 1,725 acres in Trego County were covered by ground-water rights, or

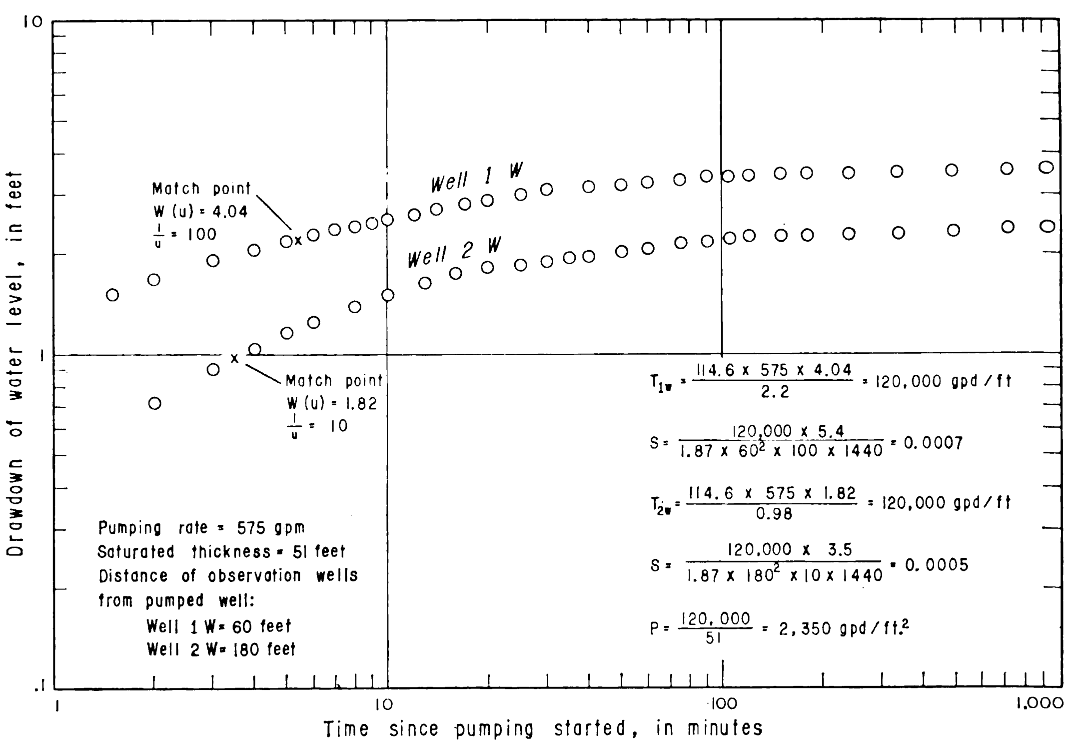

FIGURE 14.—Drawdown of water levels in observation wells during aquifer test, plotted against time since pumping started (well 12-23-30acc).

applications for rights, for which 3,487 acre-feet of ground water per year was appropriated, as of April 1963. Surface-water rights, or application for rights, totaled 1,105 acres, for which 2,119 acre-feet of surface water per year was appropriated. This does not include water released from Cedar Bluff reservoir for irrigation districts below the reservoir.

Possibilities of Developing Additional Supplies

Most of the land irrigated with ground water in Trego County is in Big Creek valley. On the assumption that the alluvium and Wisconsinan terrace deposits of Big Creek valley have an average width of a half mile, a length of 30 miles, an average thickness of saturated material of 20 feet, and a specific yield (ratio of the volume of water the saturated part of the aquifer will yield, by gravity, to its own volume) of 15 percent, there would be about 30,000 acre-feet of water in storage, which is 1,500 times the amount of water pumped for irrigation in Big Creek valley in 1962 (as reported to the Division of Water Resources of the Kansas State Board of Agriculture). If pumping were increased enough to lower the water table below stream level, the ground-water reservoir would be recharged from the stream instead of discharging into the stream as it does now. It is estimated that about equal amounts of ground water are in storage in each of the three principal valleys in the County—Smoky Hill Valley, Saline Valley, and Big Creek valley.

About 300 square miles in the northern and central parts of Trego County are underlain by the Ogallala Formation in which the estimated average saturated thickness is about 25 feet. Assuming a specific yield of 15 percent, the ground water in storage in this area would be about 700,000 acre-feet. Not all this water could be pumped from the aquifer, and yields from wells are only moderate to low, but it is an important source of water in the area.

Cedar Bluff Reservoir

Cedar Bluff Reservoir on the Smoky Hill River was filled in 1951 soon after construction of the dam was completed. The height of the dam is 134 feet above the river; its length is 12,560 feet. The reservoir is approximately 9 miles long and nearly 5 miles wide at its widest point. It has a shoreline of about 54 miles at irrigation-pool level. The reservoir has a flood-storage capacity of 191,800 acre-feet and an irrigation-storage capacity of 176,800 acre-feet.

MINERAL RESOURCES

Mineral resources of Trego County, other than soil and ground water, include oil, construction materials, and volcanic ash.

Oil

Trego County has been explored for oil since 1923. Oil was first discovered in May, 1929, in sec. 20, T 13 S, R 21 W. Production was from the basal conglomerate of Pennsylvanian age at a depth of 3,960 to 3,972 feet. Named the Rega pool, it was soon abandoned after producing about 15,000 barrels of oil. The pool was revived with a producer in 1947, but was abandoned again in 1950. The WaKeeney pool, discovered in 1934 in the northern part of the County, was the second pool discovered. Production was from the Lansing Group of Pennsylvanian age. The Gugler pool was discovered in 1936 about 4 miles northeast of the Rega pool. Production was from rocks of Pennsylvanian age and from Arbuckle rocks of Cambrian and Ordovician age. No new pools were discovered until 1941, when the Ogallah pool was opened about 4 miles north of the Gugler pool. Further development of the oil industry in Trego County is summarized in Table 2.

The 1963 production from 331 wells in 29 fields was 1,582,000 barrels of oil. Cumulative production to the end of 1963 was almost 19 million barrels. Gas in commercial quantities has not been produced in Trego County. Yearly data on production of oil and gas in Kansas are available in the files of the Oil and Gas Division of the State Geological Survey of Kansas and are published as bulletins of the State Geological Survey of Kansas.

Table 2.—Number of producing wells and producing fields, and annual production of oil from 1938 to 1963 in Trego County, Kansas.

Year	Producing wells	Producing fields	Production, thousands of barrels	Year	Producing wells	Producing fields	Production, thousands of barrels
1938	13	2	326*	1951	51	10	264
1939	13	2	43	1952	110	14	802
1940	8	2	48	1953	139	20	1,032

1950	18	7	90	1963	331	29	1,582

* Cumulative production to the end of 1938.
Data from Bulletins of the State Geological Survey of Kansas, annual oil and gas development reports.

Construction Materials

MIXED AGGREGATE

Deposits of sand and gravel suitable as road metal for light-traffic roads and in the construction of black-top roads are abundant in Trego County. The deposits are found chiefly along the Smoky Hill Valley as terrace deposits and in the Ogallala Formation in the upland areas. Terrace deposits along the Smoky Hill Valley are predominantly sand and gravel and are more suitable for mixed aggregate than are terrace deposits along other streams in the County, which in places contain considerably more silt with little or no sand and gravel.

CONCRETE AGGREGATE

Aggregate for concrete should be free from adherent coatings or silt and clay particles that would interfere with bonding. Arkosic sand and gravel in terrace deposits along the Smoky Hill Valley are generally suitable for concrete aggregate, although if silicious materials such as opaline or chalcedonic chert is present in significant quantities, a low-alkali cement may be necessary.

STRUCTURAL STONE

The Fort Hays Limestone Member of the Niobrara Chalk has been quarried for structural stone at numerous localities in Trego County. The Fort Hays is relatively soft, although it hardens upon weathering. The Fort Hays also tends to absorb water and thus to deteriorate through freeze-and-thaw action and from spalling. Many farm buildings, city dwellings, and business houses in the area constructed of the Fort Hays Limestone seem to stand up well for many years, however. In a report by Risser (1960) the sources and characteristics of building stone in Kansas are discussed.

Volcanic Ash

Volcanic ash in Trego County consists predominantly of minute, platy or curved fragments of volcanic glass. The ash is generally white to light pearly-gray, but occasionally may show tints of yellow or red. The most common uses of volcanic ash are as an ingredient of ceramic glazes, as an additive to certain types of concrete, and as a mineral filler for bituminous-surfaced highways.

A small pit of volcanic ash has been opened in the SE sec. 36, T 14 S, R 21 W. About 10 feet of ash is present, with the lower 6 feet relatively free of impurities. The deposit becomes thinner laterally from the pit. Only a small amount of ash has been taken from the pit. Two other ash deposits were noted—one in the SE sec. 28, T 14 S, R 21 W, and another in the SW sec. 30, T 14 S, R 22 W. These deposits are small and have little commercial value.

QUALITY OF GROUND WATER

The chemical character of the ground water in Trego County is indicated by analyses of samples from wells deriving water from the principal aquifers (Table 3). The analyses of water were made by Howard A. Stoltenberg, Chief Chemist, in the Sanitary Engineering Laboratory of the Kansas State Department of Health. The results of the analyses are given in parts per million. Factors for converting parts per million of mineral constituents to equivalents per million are given in Table 4. The analyses show only the dissolved mineral constituents and do not indicate the sanitary condition of the water. Representative analyses of ground water from the principal aquifers are shown in Figure 15.

Table 4.—Factors for converting parts per million to equivalents per million.

Mineral constituent	Chemical symbol	Conversion factor
Calcium	Ca^{++}	0.0499
Magnesium	Mg^{++}	.0822
Sodium	Na^{+}	.0435
Potassium	K^{+}	.0256
Carbonate	CO_3^{--}	.0333
Bicarbonate	HCO_3^{-}	.0164
Sulfate	SO_4^{--}	.0208
Chloride	Cl^{-}	.0282
Fluoride	F^{-}	.0526
Nitrate	NO_3^{-}	.0161

CHEMICAL CONSTITUENTS IN RELATION TO USE

The following discussion of the chemical constituents of ground water has been adapted in part from publications of the U.S. Geological Survey and the State Geological Survey of Kansas

DISSOLVED SOLIDS

The residue that is left after a sample of water has evaporated consists mainly of the dissolved minerals in the original sample, but may also include some organic material and water of crystallization. Water containing less than 500 ppm (parts per million) of dissolved solids generally is satisfactory for domestic and many industrial purposes. Water containing more than 1,000 ppm of dissolved solids is likely to

* One part per million is equivalent to one pound of substance per million pounds of water or 8.33 pounds per million gallons of water.

contain enough of certain constituents to cause a noticeable taste or to make the water unsuitable in other respects.

The dissolved solids in the samples of water collected ranged from 229 to 2,280 ppm (Table 3). Most samples contained less than 500 ppm of dissolved solids. Eight samples contained more than 1,000 ppm of dissolved solids.

HARDNESS

Hardness of water is recognized most commonly by the amount of soap needed to produce a lather or suds and by an insoluble scum that forms during the washing process. Calcium and magnesium cause almost all the hardness of water and are the constituents that contribute to the incrustation that may develop when water undergoes changes in temperature and pressure.

The total hardness of water may be divided into two types—carbonate hardness and noncarbonate hardness. Carbonate hardness includes that portion of the calcium and magnesium that would combine with the bicarbonate and the small amount of carbonate that are present. Carbonate hardness can be virtually removed by boiling the water, thereby causing precipitation of magnesium and calcium carbonate. Noncarbonate hardness is the difference between the total and the carbonate hardness and is caused by that portion of calcium and magnesium that would combine with the sulfate, chloride, and nitrate ions that are present, plus the slight hardness effect of other minor con-

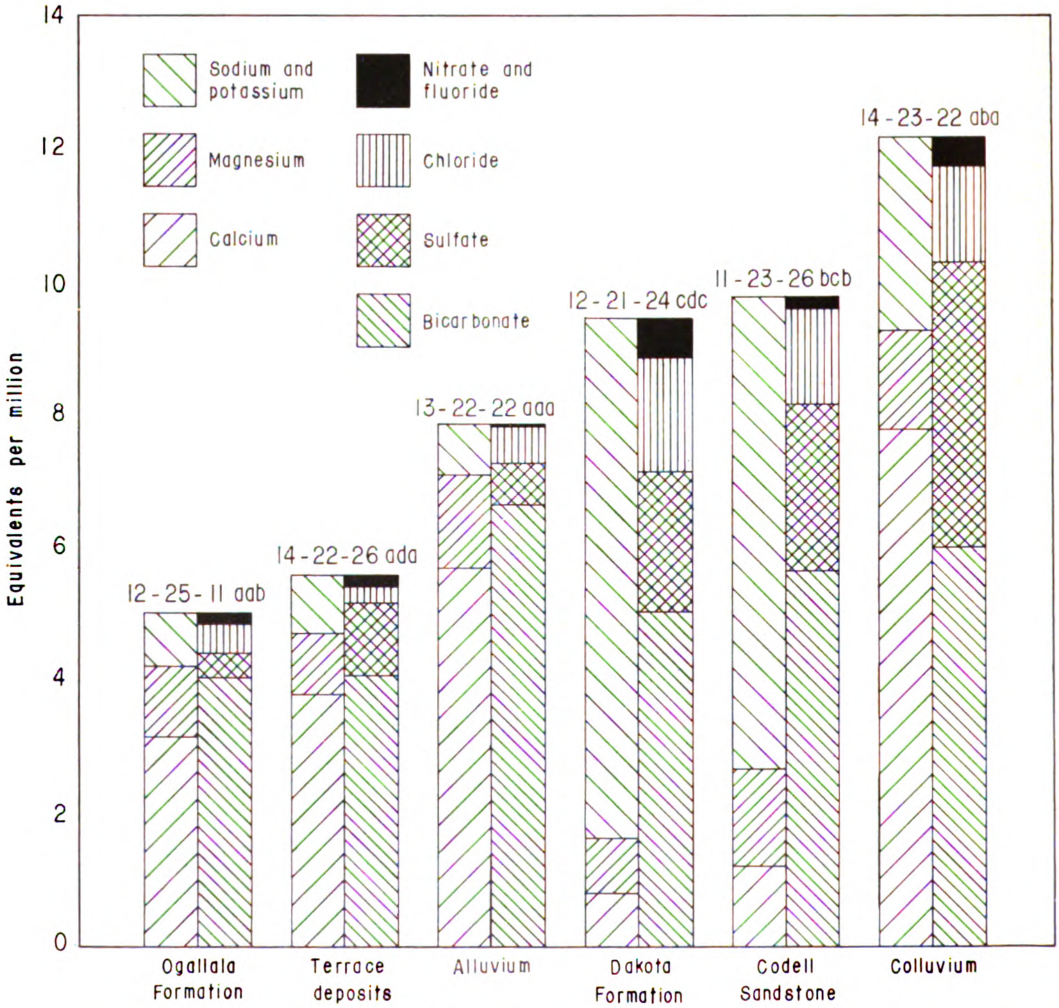

FIGURE 15.—Graphic representation of chemical constituents in samples of water from wells in principal aquifers in Trego County, Kansas.

stituents. Noncarbonate hardness cannot be removed by boiling.

Water that has a hardness of less than 60 ppm is classified as soft. Hardness of 60 to 120 ppm will cause an increase in the amount of soap required for washing but will not interfere with the use of the water for most purposes—although water in the upper part of this range will cause considerable scale in steam boilers. Hardness of 120 to 180 ppm will cause a hardness that is quite noticeable. Water that has a hardness of more than 180 ppm is considered very hard. Where municipal water supplies are softened, the hardness is generally reduced to about 100 ppm.

Most samples of the water collected were high in total hardness (carbonate and noncarbonate). Most of them ranged from 100 to 400 ppm, with the greatest proportion ranging from 200 to 300 ppm. Only four samples had a total hardness of less than 100 ppm (Table 3).

NITRATE

The nitrate content of natural water may vary greatly, and in many ground waters nitrates may seem unrelated to any geologic formation. Although some nitrate may be derived from nitrate-bearing rocks and minerals in the water-bearing formation, strong concentrations of nitrate probably are due to other sources. Nitrates are dissolved readily from soils that contain nitrate concentrations derived from plants, nitrate fertilizer, animal waste, or nitrifying bacteria. High nitrate concentrations in water may be due to the flow of surface water into a well. In an area where privies, cesspools, and barnyards are sources of organic nitrogen, a large amount of nitrate in well water may indicate harmful bacteria or pollution.

In the last two decades, investigations into the effects of nitrate on the human system have shown that too much nitrate in water may cause cyanosis in infants (so-called "blue babies") when the water is taken in directly or used in the preparation of the formula for feeding. Both the Kansas State Department of Health and the U.S. Public Health Service regard 45 ppm as the safe limit of nitrate (as NO_3). This amount of nitrate is equivalent to 10 ppm of nitrogen. Water containing as much as 90 ppm of nitrate generally is considered very dangerous to infants, and water containing as much as 150 ppm may cause severe cyanosis. Moderate nitrate concentrations seemingly are not harmful to older children or adults. Nitrate cannot be removed from water by boiling.

The nitrate content of the samples of water collected ranged from less than 1 ppm to 348 ppm (Table 3). Most samples were low in nitrate content although eight samples ranged between 45 and 90 ppm and three exceeded 150 ppm.

FLUORIDE

Fluoride generally is present only in small amounts in ground water. However, the fluoride content of drinking water should be known because if children drink water containing too much fluoride during the formation of permanent teeth, mottling of the enamel may result. If the fluoride content is as much as 4 ppm, about 90 percent of the children using the water may develop mottled tooth enamel (Dean, 1936). Although too much fluoride has a detrimental effect, a smaller amount in drinking water, about 1 ppm, lessens the incidence of tooth decay (Dean, *et al.*, 1941). The U.S. Public Health Service (1962) recommends the standards for content of mineral constituents in drinking water that are to be used on interstate carriers. The recommended ***maximum*** content for fluoride is 1.5 ppm.

The fluoride content of the samples of water collected ranged from 0.06 to 5.2 ppm (Table 3). Although most samples contained less than 1.0 ppm, seven samples exceeded 1.5 ppm. Of five analyses of water from the Dakota Formation, four exceeded 1.5 ppm of fluoride.

CHLORIDE

Chloride is abundant in nature and many rocks contain small to large amounts of chloride salts which may be dissolved by ground water. Chloride has little effect on the suitability of water for ordinary use, unless present in such concentrations as to make the water nonpotable or corrosive. Water that contains less than 150 ppm of chloride is satisfactory for most purposes. Water containing more than 250 ppm generally is objectionable for municipal supplies, and water containing more than 350 ppm is objectionable for most irrigation or industrial uses; water containing 500 ppm has a disagreeable taste. However, animals can tolerate water with a much greater chloride concentration (*e.g.*, concentrations of as much as 4,000 to 5,000 ppm can be tolerated by cattle.)

The chloride content of the water samples collected ranged from 7 ppm to 368 ppm (Table 3). Most samples were low in chloride; all but three samples contained less than 100 ppm.

IRON

Iron and manganese in quantities that exceed a few tenths of a part per million are undesirable, as they stain fabrics and plumbing fixtures and produce an objectionable coloration and taste in the water. Water in the ground may contain considerable iron in the ferrous state, but upon exposure to air most of the iron is oxidized and precipitated as reddish-brown ferric hydroxide. Iron can be removed from most water by aeration and filtration, but some water requires additional treatment. Drinking water standards recommended by the U.S. Public Health Service are that the iron content should not exceed 0.3 ppm and that the manganese content should not exceed 0.05 ppm.

The iron content of the water samples collected ranged from 0.03 to 4.7 ppm (Table 3). Most samples contained less than 0.3 ppm of iron, but three samples contained more than 1.0 ppm.

SULFATE

Sulfate (SO_4) in ground water is derived principally from gypsum or anhydrite (calcium sulfate) and from the oxidation of pyrite (iron disulfide). Magnesium sulfate (Epsom salt) and sodium sulfate (Glauber's salt), if present in sufficient quantities, impart a bitter taste to the water, and the water may act as a laxative on people not accustomed to drinking it. More than 250 ppm of sulfate in drinking water generally is undesirable.

Most water samples collected were low in sulfate, although nine samples exceeded 250 ppm and one exceeded 1,000 ppm of sulfate (Table 3).

SILICA

Silicon combined with oxygen in the form of SiO_2 is called silica. Silica is a mineral constituent in most ground waters. Except for the scale it may form, silica has little effect on the use of water for most purposes. Silica may be deposited as scale with other incrustants, generally in the form of calcium or magnesium silicate. The silica content of the water samples collected ranged from 8 to 45 ppm (Table 3). Analyses of water from both the Dakota Formation and the Codell Sandstone Member of the Carlile Shale were characteristically low in silica content.

BICARBONATE

Bicarbonate and carbonate cause alkalinity of ground water. The concentration of bicarbonate, the predominant anion in the samples of water from Trego County, ranged from 194 to 415 ppm (Table 3).

SODIUM

The sodium content of water used for irrigation is important because a large percentage of sodium (equivalents per million of sodium divided by total equivalents per million of sodium, potassium, calcium, and magnesium) has an adverse effect on soil, especially where leaching is not adequate. The effect of sodium in irrigation water is discussed in detail in U.S. Department of Agriculture Handbook 60 (U.S. Salinity Laboratory Staff, 1954).

Analyses of water samples from 10 wells deriving water from alluvium, terrace deposits, and the Ogallala Formation were used to illustrate the suitability of water for irrigation. The procedure is based upon methods outlined in U.S. Department of Agriculture Handbook 60.

Figure 16 shows sodium-adsorption ratios determined by plotting the sodium content (equivalents per million) on the left scale (A), and the calcium plus magnesium content (equivalents per million) on the right scale (B). The point at which a line connecting these two points intersects the sodium-adsorption-ratio scale (C) indicates the sodium-adsorption ratio

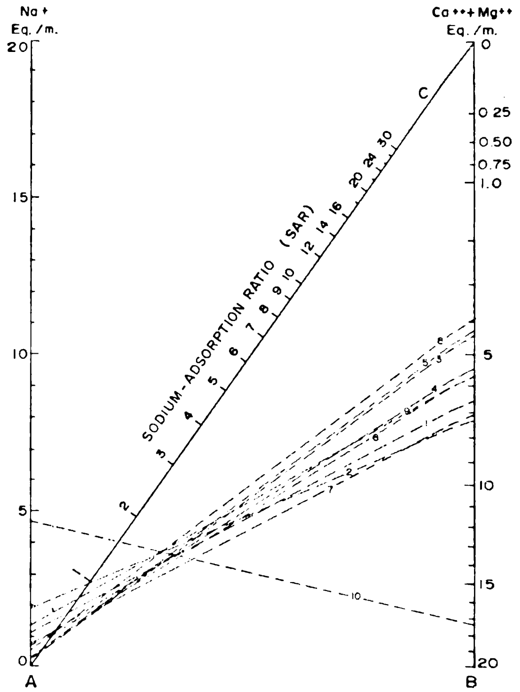

FIGURE 16.—Nomogram for determining the sodium-adsorption ratio of water.

TABLE 5.—Sodium-adsorption ratios (SAR), conductivities, sodium content, and calcium plus magnesium content of water samples from selected wells.

Well number	Sample used in Figures 16 and 17	Na (equivalents per million)	Ca + Mg (equivalents per million)	SAR	Conductivity (micromhos per centimeter at 25°C)

12-24-5cdc	6	.57	5.67	.30	650
13-22-22aaa	7	.76	7.09	.40	740
13-23-17aaa	8	.55	3.94	.40	420
14-24-25ddd	9	1.37	5.68	.80	720
14-25-25ccb	10	4.63	17.30	1.60	1,950

of the water. Table 5 gives sodium-adsorption ratios, electrical conductivities, and values for sodium and for calcium plus magnesium of the water samples for which analyses were plotted.

The specific conductance of a water sample can be measured directly in the laboratory, or it can be approximated by multiplying the total equivalents per million of the cations (calcium, magnesium, sodium, and potassium) by 100, or by dividing the dissolved-solids content in parts per million by 0.64.

Sodium-adsorption ratios and electrical conductivities are plotted in Figure 17 to provide a classification of waters for irrigation use. Low-sodium water (S1) can be used for irrigation on most soils with little danger of development of harmful levels of exchangeable sodium. Medium-sodium water (S2) may be used safely on coarse-textured or organic soils having good permeability, but S2 water will present an appreciable sodium hazard in certain fine-textured soils, especially under poor leaching conditions. High-sodium water (S3) may produce harmful levels of exchangeable sodium in most soils and will require special soil-management techniques, such as good drainage, leaching, and additions of organic matter. Very high-sodium water (S4) generally is unsatisfactory for irrigation unless special practices are followed, such as addition of gypsum to the soil.

Low-salinity water (C1) can be used for irrigation of most crops on most soils with little likelihood that soil salinity will develop. Medium-salinity water (C2) can be used if a moderate amount of leaching occurs. Crops that tolerate moderate amounts of salt, such as potatoes, corn, wheat, oats, and alfalfa, can be irrigated with C2 water without special practices. High-salinity water (C3) cannot be used on soils having restricted drainage. Very high-salinity water (C4) can be used only on certain crops and then only if special practices are followed. In Figure 17, all the waters were classified as low-sodium water (S1) and either medium-salinity water (C2) or high-salinity water (C3).

SANITARY CONSIDERATIONS

The analyses of water in Table 3 give only the dissolved-solids content of the water and do not indicate the sanitary quality of the water, although a large amount of certain mineral constituents, such as nitrate or chloride, may indicate pollution. Water containing mineral matter that imparts an objectionable taste or odor may be free from harmful bacteria and quite

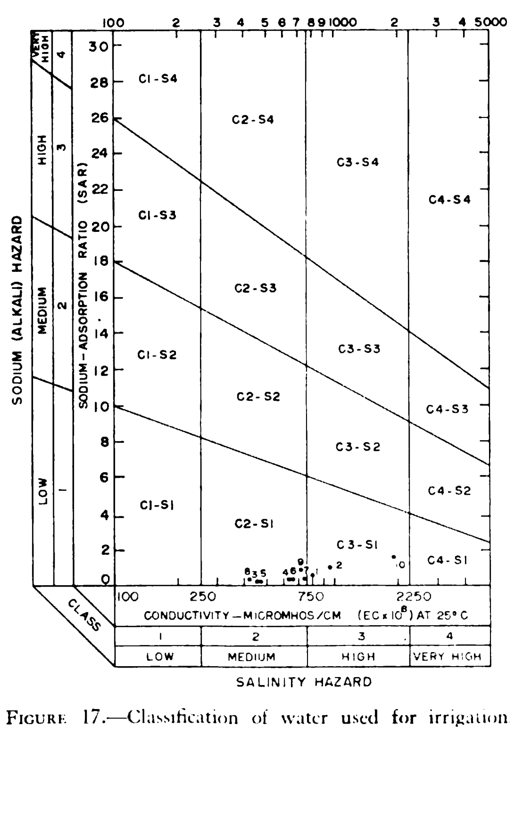

FIGURE 17.—Classification of water used for irrigation.

safe for drinking. Conversely, water that is clear and pleasant to the taste may contain harmful bacteria. Great care should be taken to protect domestic and public water supplies from pollution. To guard against contamination, a well must be properly sealed to keep out dust, insects, vermin, debris, and surface water. Wells should not be placed where barnyards, privies, or cesspools are possible sources of pollution.

GEOLOGIC FORMATIONS IN RELATION TO GROUND WATER

CRETACEOUS SYSTEM— LOWER(?) CRETACEOUS SERIES

Dakota Formation

The Dakota Formation [Early(?) Cretaceous] does not crop out in Trego County, but it contains water within a practical drilling depth. In certain areas where shallow ground waters are scarce or not available, the Dakota is an important source of ground water.

The term "Dakota group" (Meek and Hayden, 1862) was first applied to the varicolored clay, sandstone, and lignite beds underlying the "Benton group" in exposures near Dakota City, Dakota County, Nebraska. The use of this grouping has been discontinued (Plummer and Romary, 1942), and the Dakota Formation now includes strata lying between the Kiowa Shale below and the Graneros Shale above. The Dakota Formation as defined by the State Geological Survey of Kansas has been variously referred to as "Dakota group" (Meek and Hayden, 1862); "Dakota sandstone" (Prosser, 1897); "Dakota formation" (Twenhofel, 1924); and "Cockrum sandstone" (Latta, 1941). Rubey and Bass (1925) referred to the upper 125 feet of the Dakota in Russell County as the "Rocktown channel sandstone member." Merriam (1957) used the term "Omadi formation" for the Dakota Formation in the subsurface of western Kansas.

CHARACTER AND SUBDIVISIONS

In Kansas the Dakota Formation has been divided into two members (Plummer and Romary, 1942), the lower called the Terra Cotta Clay Member and the upper called the Janssen Clay Member. Plummer and Romary described the Dakota Formation as consisting chiefly of varicolored clay containing irregular, lenticular beds of siltstone and sandstone. The lower member is dominantly gray and red mottled clay. A zone of siderite, limonite, and hematite pellets marks the base of the upper member. Gray clay containing siderite pellets and yellow-orange coloring matter dominates the upper member, with lignite common in the upper part. Lenticular beds of sandstone occur throughout the Dakota Formation.

The Dakota Formation is present in the subsurface throughout the County. The depth to the Dakota ranges from about 300 feet below the land surface in the southeastern part of the County to about 1,000 feet below the land surface in the northwestern part.

THICKNESS

The thickness of the Dakota Formation is not uniform, probably because of the disconformity at the base. Frye and Brazil (1943, table 3) gave the thickness of the Dakota Formation in Ellis and Russell counties as 200 to 300 feet. Swineford and Williams (1945) gave a thickness of 213 to 300 feet for the Dakota in southwestern Russell County. Latta (1950) indicated the Dakota was 200 to 300 feet thick in northern Barton County. Hodson (1959) gave a thickness of about 350 for the Dakota near the Mitchell-Cloud county line. Leonard and Berry (1961) indicated that in southern Ellis County the thickness of the Dakota was only 155 feet. Hodson and Wahl (1960) gave a thickness of about 250 feet for the Dakota in Gove County. A study of drillers' logs indicated a thickness of 150 to 250 feet for the Dakota Formation in Trego County.

WATER SUPPLY

In the east-central and southern parts of Trego County, a number of wells obtain water for domestic and stock use from the Dakota Formation. Information on eight wells ranging in depth from 500 to 670 feet that derive water from the Dakota is given in Table 6, and chemical analyses of five water samples from the Dakota are given in Table 3. Water from the Dakota is more mineralized than water in the unconsolidated rocks, but generally the water is soft.

Depth to the water level in wells ranged from about 200 feet to about 400 feet below the land surface for wells obtaining water from the Dakota that were inventoried in this investigation. The sandstone lenses in the Dakota contain ground water under artesian pressure, and, although locally there are differences in hydrostatic pressure from well to well (Leonard and

Berry, 1961, p. 26), ground-water investigations in much of Kansas suggest a connected hydrologic system among the sandstone lenses, for the most part.

Wells in the Dakota Formation in Trego County yield only quantities of water sufficient for domestic or stock supplies, although in some other areas in Kansas wells penetrating thick sandstones in the Dakota yield moderately large quantities of water, generally in areas nearer Dakota outcrops.

CRETACEOUS SYSTEM—UPPER CRETACEOUS SERIES

Graneros Shale

The Graneros Shale overlies the Dakota Formation and consists chiefly of dark-gray to black noncalcareous shale. The Graneros is present in the subsurface of Trego County where drillers' logs indicate it is 40 to 50 feet thick. It yields no water to wells in Trego County.

Greenhorn Limestone

The Greenhorn Limestone overlies the Graneros Shale and consists principally of about 100 feet of alternating thin beds of chalky limestone and calcareous shale. The Greenhorn Limestone is divided into four members, which, in ascending order, are the Lincoln Limestone, Hartland Shale, Jetmore Chalk, and Pfeifer Shale (Rubey and Bass, 1925; Bass, 1926). The chalky limestone and shale that comprise the Greenhorn are relatively impervious and do not yield water to wells in Trego County.

Carlile Shale

The Carlile Shale, consisting of the Fairport Chalk, the Blue Hill Shale, and the Codell Sandstone members, is the oldest formation exposed in Trego County. Only the upper part of the Carlile crops out, chiefly along the Smoky Hill Valley in the southern part of the County.

CHARACTER AND SUBDIVISIONS

The Carlile Shale was named by Gilbert (1896) from exposures of gray argillaceous shale west of Pueblo, in Pueblo County, Colorado. Logan (1897) correlated Gilbert's section with Cretaceous rocks in north-central Kansas. Rubey and Bass (1925) divided the Carlile Shale into two members, the "Fairport chalky shale" below and the "Blue Hill shale" above. The Codell Sandstone Member (upper part of the Carlile Shale) was named by Bass (1926) from exposures along the Saline River in Ellis County, Kansas.

The Fairport Chalk, lowermost member of the Carlile Shale, consists of alternating beds of calcareous shale and thin, nodular, chalky limestone. The Fairport does not crop out in Trego County.

The Blue Hill Shale, middle member of the Carlile Shale, is the oldest rock unit exposed in Trego County. The Blue Hill crops out along the Smoky Hill Valley eastward from the junction of the Smoky Hill River and Hackberry Creek. The Blue Hill is well exposed on the steep slopes below the escarpment made by the Niobrara Chalk. Because the shale is soft, however, good exposures are rare elsewhere.

The Blue Hill Member is a blocky to fissile, clayey shale that characteristically weathers into small, brittle flakes. The predominant color of the shale is dark blue-gray, but locally the shale is light to dark olive-gray. Drill cuttings from the Blue Hill may be very dark-gray to black as shown in several logs of test holes at the end of this report. Thin lenses of siltstone, fine-grained sandstone, and sandy shale are common in the upper part of the Blue Hill and become more abundant upward.

Concretions characterize outcrops of the Blue Hill. Most of the concretions are found in zones and become much more abundant in the upper part. Most of the concretions are calcareous septarian concretions, but noncalcareous clay-ironstone concretions are common, and, locally, calcareous sandstone concretions are found. The concretions range in diameter from a few inches to as much as 3 feet. Most are ellipsoidal or discoidal, but smaller concretions may be nearly spherical. The concretions contain intersecting veins of brown calcite that on weathering tend to stand out in relief.

The Codell Sandstone Member marks the top of the Carlile Shale. In Trego County, outcrops of the Codell consist of a zone of rust-brown fine sand, sandy silt, and clayey silt. It is generally very argillaceous; shark teeth and bone fragments are common in it. In fresh exposures, the Codell is light gray to gray. Specks of disseminated limonite cause an orange to yellowish-brown coloration in weathered outcrops. The contact between the Codell and the underlying Blue Hill Shale Member is gradational, whereas the contact between the Codell and the overlying Fort Hays Limestone Member of the Niobrara Chalk is generally sharp.

The thickness of the Codell Sandstone Member changes laterally in Trego County, but usually about 2 or 3 feet of Codell is present. Locally, however, as much as 5 feet of sandy silt representing the Codell was observed, while at a few localities, only a few inches was noted. A study of drillers' logs indicated that in the northeastern part of the County, the Codell may be as much as 20 feet in thickness. Hattin (1962) reported a thickness of nearly 20 feet in northern Ellis County, along the Saline Valley.

DISTRIBUTION AND THICKNESS

The Carlile Shale crops out along the Smoky Hill Valley eastward from the mouth of Hackberry Creek. Drillers' logs indicate that the Carlile is nearly 300 feet thick and that the Blue Hill Shale Member comprises about two-thirds of the formation.

WATER SUPPLY

The Codell Sandstone Member yields water to a number of wells in Trego County, mostly in the eastern and southern parts. Information on 19 wells ranging in depth from 31 feet to 320 feet below the land surface is given in Table 6, and chemical analyses of six water samples from the Codell are given in Table 3. The Codell yields only small amounts of water to wells, although the yield is generally adequate for domestic and stock supplies.

In the southern part of the County, where in much of the area only meager amounts of shallow ground water are available, small amounts of ground water are obtained from shallow wells dug or drilled into colluvium and into the underlying weathered shale and sandy shale of the upper part of the Blue Hill Shale Member.

Niobrara Chalk

The Niobrara Chalk was named by Meek and Hayden (1862) from exposures of calcareous marl and chalky limestone near the mouth of the Niobrara River in northeastern Nebraska. Logan (1897) described the Niobrara in north-central Kansas and divided it into the Fort Hays Limestone Member below and the Smoky Hill Chalk Member above.

The Niobrara Chalk consists chiefly of alternating beds of light-gray chalk, chalky limestone, and chalky shale. The total thickness of the Niobrara in west-central Kansas is about 700 feet, but only the lowermost 400 to 500 feet is present in Trego County, the upper part having been removed by erosion.

FORT HAYS LIMESTONE MEMBER

The Fort Hays Limestone Member is distinguished from the Smoky Hill, upper member of the Niobrara Chalk, by the relative predominance of massive beds of chalk and chalky limestone 50 to 60 feet in thickness. The chalky limestone beds in the Fort Hays generally range from 1 to 5 feet in thickness and are separated by thin partings of chalky shale. These beds contain large *Inoceramus* and small *Ostrea* shells. The Fort Hays is characteristically grayish-white, but locally may be stained yellow or light brown on the outcrop. The Fort Hays is more resistant to erosion than the overlying Smoky Hill Chalk Member and tends to form shoulders along slopes. Steep cliffs, in places nearly vertical, are typical of the Fort Hays along the Smoky Hill Valley. In the southeastern and extreme southern parts of the County, the Fort Hays forms prominent escarpments. The Fort Hays has been quarried at places along the outcrop for building stone and for road metal.

SMOKY HILL CHALK MEMBER

The Smoky Hill Chalk Member consists principally of thin-bedded chalk and chalky shale, with thin beds of bentonite throughout. Fresh exposures are platy and light to dark gray, but the beds weather colorfully to white, orange, and brown. Concretions of limonite and pyrite are common, and they account for the bright colors of the Smoky Hill when weathered. Thin veins of gypsum are characteristic of outcrops.

The Smoky Hill Chalk Member is noted for the abundant fossils it contains. Vertebrate fossils include bones of aquatic reptiles, such as mosasaurs and plesiosaurs, and numerous fish remains. Sharks' teeth are common. Invertebrate fossils characteristically include the phyla Mollusca and Echinodermata, the most numerous of which are the genera *Inoceramus*, a clam, and *Ostrea*, an oyster. Minute shells of foraminifers belonging mainly to the families Globigerinidae and Textulariidae comprise much of the chalk.

The Smoky Hill is also notable for its effect on topography. Soil development is either thin or absent, vegetation is sparse, and rainwash and gully erosion produce a badlands type of topography.

WATER SUPPLY

The Niobrara Chalk is not important as an aquifer in Kansas and carries very little ground water in Trego County. The beds of shaly chalk are relatively impermeable, and water is transmitted chiefly through fractures and joints and is found only locally and in small quantities. Fractures filled with secondary calcite are indicative that water has circulated through the formation at some time in the past. Where the Niobrara was observed to be fractured, however, it was generally in the topographically higher parts of the County well above the water table. Fractures and bedding planes are more prevalent in the Fort Hays Limestone Member, and these may yield small amounts of ground water to a few wells.

NEOGENE SYSTEM—PLIOCENE SERIES

Ogallala Formation

The Ogallala Formation was named by Darton in 1899 (p. 732-734) from exposures in southwestern Nebraska. Darton (1920, p. 6) designated the type locality as being near Ogallala Station in western Nebraska. Since Darton's work, the most significant studies of the Ogallala in western Kansas have been by Elias (1931), Smith (1940), and Frye, Leonard, and Swineford (1956).

CHARACTER AND SUBDIVISIONS

The Ogallala Formation in Kansas is divided into three members which, in ascending order, are the Valentine, Ash Hollow, and Kimball. A thin, discontinuous pisolitic limestone, 1 to 3 feet thick, commonly occurs as the topmost bed of the Ogallala. No attempt was made to divide the Ogallala Formation in Trego County, and it is shown on Plate 1 as a single unit.

The Ogallala Formation constitutes a widespread mantle of fluvial deposits consisting predominantly of sand, gravel, silt, and clay. The Ogallala was deposited upon an erosional surface of Upper Cretaceous rocks by eastward-trending streams whose source of sediment was igneous rocks of the Rocky Mountains and sedimentary rocks of eastern Colorado. The deposits are comprised chiefly of a series of valley fillings overlapping laterally from the axes of the main drainageways onto the gentle erosional slopes of the valley sides. Thus, the Ogallala Formation consists of a heterogeneous complex of predominantly clastic deposits, with textures ranging from very coarse gravel and pebbles to clay and sorting ranging from good to poor. The lithology changes sharply both vertically and laterally. Lentils of volcanic ash, marl, or marly limestone, and bentonite contrast with the predominantly stream-laid clastics. Throughout this heterogeneous assortment of sediments there is virtually no distinctive bed that can be traced any appreciable distance.

The deposits are interbedded and admixed in various proportions and are largely unconsolidated, although cementation of beds occurs to some degree throughout the Formation. Calcium carbonate is a common constituent throughout almost all of the Ogallala. It is distributed both as fine material and as stringers of caliche and small- to medium-sized nodules. Calcium carbonate in many places binds the deposits so firmly as to produce a series of hard ledges, interbedded with beds that are only slighted cemented. The hard ledges are usually unevenly cemented and form roughly weathered benches and cliffs which resemble mortar and accordingly are often referred to as "mortar beds." Silica also is present as a cementing material in beds of opaline sandstone or as chert deposits, and variously colored chert in the form of nodules or small, irregular lenses and beds is occasionally seen.

Sand, the principal material within the Ogallala Formation, is present at all horizons and is typically light-gray or greenish in color. Beds of uniform sand may occur, but generally the sand ranges from fine to coarse and commonly is mixed with gravel, silt, or clay. Gravel beds containing lenses of sand, silt, and clay are common, but thick beds of uniform gravel are rare. Beds of sand and gravel with distinct cross-bedding occur in places. Silt, sandy silt, and clayey silt are present throughout the Ogallala and are greenish-gray, pink, tan, and gray; if the beds contain a large amount of calcium carbonate, they are light gray or white. Lenses and thin beds of white and pinkish limestones are common in the middle and uppermost parts of the Ogallala. Bluish-gray volcanic ash is found locally in the lower and middle parts of the Formation.

The Formation's topographic expression includes flat uplands, gentle erosional slopes, and nearly vertical cliffs. In spite of the diversity of deposits, the outcrop pattern of the Ogallala presents a uniformity of aspect that makes it readily identifiable. Typical outcrops are cemented to various degrees and are ash gray in color. Because the cemented beds are more resistant to erosion, many outcrops of the Ogallala form rough benches, hard ledges, and cliffs; exposed surfaces commonly have a knobby, irregular aspect.

Opinions differ regarding the origin of the thin, discontinuous bed of pisolitic limestone, originally called the "algal limestone" by Elias (1931), which marks the stratigraphic top of the Ogallala Formation. Elias postulated a lacustrine origin for the capping limestone. Subsequent workers advanced an hypothesis of subaerial origin, such as a caliche zone. Smith

(1940) discussed the two hypotheses, and more recently Frye, Leonard, and Swineford (1956, p. 13-16) critically discussed the bed, postulating a mode of origin in which development of a mature to senile lime-accumulating soil was later modified by solution.

DISTRIBUTION AND THICKNESS

The Ogallala Formation, although generally mantled with eolian silts, underlies much of the interstream areas. The Ogallala is thickest and most extensive in the central and northwestern parts of the County. It crops out along the bluffs of Big Creek valley and locally is well exposed in many of the tributary canyons along the Saline River valley. The Ogallala is thin and discontinuous in the southern part of the County due to erosion by the Smoky Hill River and its tributaries. In Trego County, the Formation rests on an erosional surface of considerable relief, which slopes generally eastward (Fig. 18).

Logs of test holes show that the thickness of the Ogallala Formation in Trego County exceeds 150 feet in some of the thicker sections. The thickness is not uniform, however, because of unconformable contacts at the top and bottom of the Formation. The thickness and character of the Ogallala Formation are shown in the *Logs of Test Holes and Wells* at the end of this report and are illustrated in the cross sections on Plate 2.

WATER SUPPLY

The Ogallala Formation is the most widespread water-bearing formation in Trego County. It supplies water to most domestic and stock wells in the County. In much of the central and northwestern parts of the County, the saturated thickness of the Ogallala is great enough to store fairly large quantities of ground water, from which moderate yields of water are obtained. In the southern part of the County, the Ogallala is either missing or thin and contains little ground water.

A considerable amount of the Ogallala has been removed by erosion along the three principal streams—the Smoky Hill and Saline Rivers and Big Creek (Pl. 2). Few areas in the County have much more than 50 feet of saturated thickness and the saturated thickness of the Ogallala decreases toward the edge of the upland where the Ogallala has been completely drained of ground water. Nevertheless it is estimated that about 700,000 acre-feet of ground water is in storage in the Ogallala in Trego County. Although yields of wells in the Ogallala are not large, it is the most important aquifer in the County because of its wide areal extent.

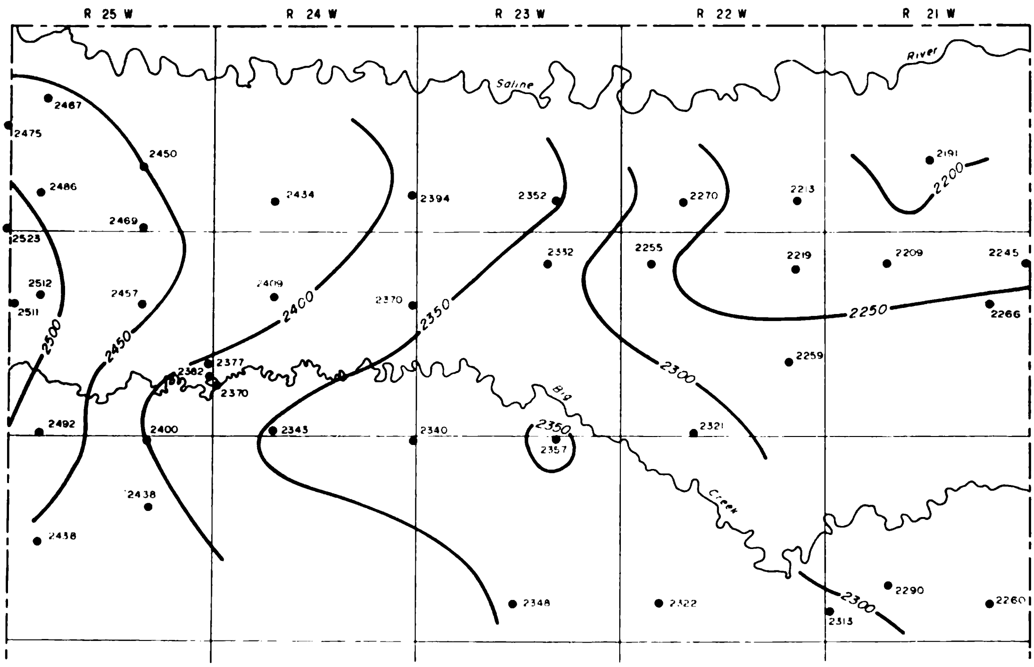

FIGURE 18.—Contours on base of Ogallala Formation in northern Trego County, Kansas (contour interval 50 feet).

NEOGENE SYSTEM—PLEISTOCENE SERIES

The classification of Pleistocene deposits by the State Geological Survey of Kansas is based on the classification of glacial deposits in the Midcontinent Region (Frye and Leonard, 1952). Although the nearest glacial deposits are more than 150 miles northeast of Trego County, correlations between the glaciated and nonglaciated areas have been made on the basis of continuous loess deposits, their molluscan fauna and buried soils, and petrologically distinctive volcanic ash (Condra, Reed, and Gordon, 1947; Frye, Swineford, and Leonard, 1948).

Deposits of Pleistocene age, although relatively thin, are the surficial materials in much of Trego County, as shown by the geologic map (Pl. 1) and cross sections (Pl. 2). Pleistocene deposits include the Grand Isand Formation and Sappa Formation of Kansan age, the Crete Formation and Loveland Formation of Illinoisan age, the Peoria Formation of Wisconsinan age, and terrace deposits and alluvium of Wisconsinan and Recent age. The Grand Island, Sappa, and Crete formations occur as terrace deposits along the valleys of the Smoky Hill and Saline rivers and along Big Creek valley. Alluvium of late Wisconsinan and Recent age occurs along the inner valleys of the larger streams. Eolian silts classified as the Peoria and Loveland formations cover much of the upland areas and extend along the outer valleys, masking the valley slopes. Pleistocene deposits have been treated in this report as terrace deposits (Crete, Sappa, and Grand Island formations), loess beds (Peoria and Loveland formations), and alluvium (late Wisconsinan and Recent deposits). Figure 6 shows the stratigraphic relation of Pleistocene deposits along the principal valleys.

Terrace Deposits

Terrace deposits shown on the geologic map accompanying this report (Pl. 1) consist chiefly of sand, gravel, and silt deposited during Kansan and Illinoisan times. Terrace deposits along the Smoky Hill Valley are predominantly sand and gravel, whereas terrace deposits along the Saline River and Big Creek valleys contain a relatively greater amount of finer clastic material with silt being predominant in the upper part. Included in the terrace deposits (Pl. 1) are the Grand Island Formation and Sappa Formation of Kansan age and the Crete Formation of Illinoisan age. The Crete and the Grand Island are lithologically similar, both consisting chiefly of arkosic sand and gravel. Stratigraphically, the Sappa Formation lies between the Crete and the Grand Island. The Sappa consists chiefly of silt and sandy silt but locally contains the Pearlette ash bed which identifies it as late Kansan in age. The Crete Formation of Illinoisan age constitutes most of what are called "terrace deposits" in this report. The Crete Formation is spread laterally over a much more extensive area than the underlying Kansan deposits, which are restricted to narrow channels.

Terrace deposits crop out extensively along the Smoky Hill Valley, but they also occur to a lesser degree along the Saline Valley and along Big Creek valley. These deposits are nearly 2 miles wide along much of the Smoky Hill Valley and in places little dissection has occurred in them, particularly along the south side of the valley in the western part of the County. Along the Saline Valley, terrace deposits are mostly remnants, since most of the deposits have been eroded. Along Big Creek valley in the central and western parts of the County, terrace deposits are of narrow width and tend to be obscured because of slope wash from the Ogallala. Along the north side of Big Creek valley in the eastern part of the County, terrace deposits are more than 2 miles wide in places. Where the terrace deposits have not been dissected by erosion, a thin cover of loess mantles them. Although the loess tends to mask the edge of the terrace deposits nearest the upland margin, these terrace deposits are a geomorphologically prominent feature in the major valleys.

GRAND ISLAND AND SAPPA FORMATIONS

The oldest Pleistocene deposits definitely recognized in Trego County are stream-deposited sand, gravel, and silt classified as the Grand Island Formation and Sappa Formation of Kansan age, although deposits penetrated in test holes 13-21-5bbc and 13-21-8abb may be Nebraskan in age. Along the Smoky Hill Valley, Kansan deposits fill a narrow channel about a quarter of a mile wide. This ancient channel, which has a meander pattern much like that of the modern river, underlies the widespread Crete Formation along much of the terrace extent of the valley, but crops out only locally. In a test hole in the SE cor. NE sec. 27, T 14 S, R 21 W, 93 feet of terrace deposits were penetrated, the lower 54 feet of which are classified as the Grand Island and Sappa Formations.

The Grand Island consists predominantly of sand and gravel containing cobbles as much as 4 inches in diameter. The sand and gravel are mostly arkosic but intermixed with the deposits are rounded chalk pebbles and shale fragments. The Sappa Formation consists mostly of silt and sandy silt, but thin lenticular beds of sand and gravel with pebbles of chalk are common. The Sappa is generally very calcareous. It is buff or light gray when fresh but characteristically weathers to very light gray. Locally, a lenticular bed of volcanic ash (Pearlette ash bed) ranging in thickness from a few inches to several feet is found within the Sappa. Outcrops of the Grand Island and Sappa formations occur in small areas along the Smoky Hill Valley.

No outcrops of Kansan deposits were found along the Saline Valley, but test drilling has shown that deposits of Kansan age underlie the Illinoisan terrace surface in a stratigraphic position analogous to that found along the Smoky Hill Valley. In a test hole drilled in the Saline Valley in the SE cor. NE sec. 9, T 11 S, R 21 W, 70 feet of terrace deposits were penetrated, the lower part of which is considered to be Kansan in age. Deposits considered to be of Kansan age were penetrated in test holes along Big Creek and underlie the Illinoisan terrace at least locally along Big Creek, especially along the north side of the valley in the eastern part of the County.

CRETE FORMATION

Deposits classified as the Crete Formation of Illinoisan age constitute most of the deposits that underlie the prominent terraces along the major valleys. The Crete Formation consists chiefly of arkosic sand and gravel. A small amount of chalk and shale pebbles and fragments are usually present but are not as common as in the Grand Island. Locally, the upper part of the Crete grades upward into yellow and buff silt and sandy silt classified as the Loveland Formation of late Illinoisan age.

WATER SUPPLY

Terrace deposits that border the principal stream valleys are generally continuous with the alluvial deposits that underlie the streams and fill the inner valleys, and the water table in the alluvium is continuous with the water table in the terrace deposits along much of the valleys. Because the terrace deposits overlie bedrock that was not cut as deeply as the incised valley of the present cycle, the saturated thickness of the terrace deposits is not as great as the saturated thickness of the alluvium of the inner valleys.

Terrace deposits yield water adequate for domestic and stock supplies at most places where they occur. In areas where the saturated material is sufficiently thick, moderately large yields from wells can be expected. Test drilling will disclose the more favorable well sites.

Peoria and Loveland Formations

CHARACTER, DISTRIBUTION, AND THICKNESS

Eolian silts (loess) of late Pleistocene age cover a considerable part of Trego County with a relatively thin mantle which tends to subdue the topography in much of the area. The loess caps the rolling hills and flat uplands and masks the gentle slopes of the valleys. It is generally thicker in the northwestern part of the County, where test-hole data indicate the loess may be 25 or 30 feet thick. The loess is shown on the geologic map (Pl. 1) as the Peoria and Loveland formations undifferentiated.

The Loveland Formation is a reddish-tan silt, mostly eolian, which characteristically grades into sand in the lower part. The Sangamon buried soil marks the top of the Loveland Formation and separates it from the overlying Peoria Formation. The Peoria is a massive, eolian, tan to gray silt, which covers much of the upland areas of Trego County.

Colluvial deposits, consisting chiefly of reworked loess, local bedrock fragments, and, in many places, sand and gravel slope wash derived from the Ogallala Formation, constitute much of the surficial material on the slopes of stream valleys and upland draws. Where these colluvial deposits are of sufficient thickness to conceal the underlying rocks they have been included with the Peoria and Loveland formations in this report.

WATER SUPPLY

The deposits mapped as Peoria and Loveland formations consist mostly of relatively thin, wind-deposited silts which generally lie above the water table. In parts of Trego County, however, where the Ogallala Formation has been removed by erosion and shallow ground-water supplies are meager, domestic and stock wells obtain small amounts of ground water from colluvial and slope deposits, which in this report are included with the Peoria and Loveland formations. In these areas, the best well sites generally prove to be in creek valleys and draws where thin alluvial and colluvial fill and unconsolidated material overlie the bedrock and serve as local catchment basins. In periods of ample rainfall these wells generally prove adequate for most domestic or stock supplies. During extended periods of dry weather, however, the water drains from much of this material and wells tend to become dry. Because ground water in colluvial deposits is generally in contact with the underlying Cretaceous bedrock and with bedrock fragments that are incorporated within the deposits, the water obtained from these wells is generally of inferior chemical quality.

Alluvium

CHARACTER, DISTRIBUTION, AND THICKNESS

Alluvium classified as late Wisconsinan and Recent in age occurs in relatively narrow deposits along the principal streams in the County. Thick, coarse alluvial deposits of sand and gravel are restricted to the larger valleys and are derived mostly by erosion of older alluvial deposits and from the Ogallala Formation. Thin, poorly sorted deposits of alluvium lie in the smaller valleys and contain relatively less coarse material, the deposits being predominantly silt and fine sand. Deposits in the smaller valleys grade headward into colluvium and slope deposits at the edge of the uplands. The lithology depends largely upon the type of rock into which the valley has been cut.

The alluvium that underlies the stream channels and the narrow floodplains along the principal streams is considered to be Recent in age. Low, relatively narrow terrace deposits, considered to be late Wisconsinan in age, border the floodplain. Although the narrow floodplain and the low terraces are best developed along Smoky Hill Valley, Saline Valley, and Big Creek valley, they are also found to a lesser extent along the smaller valleys. The alluvium of Recent age and the alluvial deposits of late Wisconsinan age underlying the low terraces are lithologically indistinguishable and are shown together as alluvium on Plate 1.

The width and thickness of the alluvium are greatest along Smoky Hill Valley, Saline Valley, and Big Creek valley. It reaches a maximum width of about a mile, but in most places it is less than a half mile in width. The alluvium generally has a thickness of 60 to 70 feet in the deepest part of the valley fill along the Smoky Hill Valley, although one test hole (14-24-35bcc) penetrated 95 feet of it. Alluvium along the Saline Valley and Big Creek valley is 40 to 50 feet thick. Alluvium in the smaller valleys is thin and of narrow extent, and headward these deposits grade into colluvium and slope wash.

WATER SUPPLY

Alluvial deposits constitute an important source of ground water in Trego County. Many domestic and stock wells obtain water from the alluvium, and most irrigation wells in the County obtain water from alluvium along the Saline River and Big Creek valleys. Moderate to moderately large yields of water can be expected from wells in alluvium along the Smoky Hill Valley.

Ground-water yields from wells in alluvium in the smaller valleys can be expected to be considerably less than in the larger valleys, because of the finer, less permeable material in the smaller valleys. Since the cross-sectional areas of the smaller valleys are small, water levels tend to fluctuate more in response to rainfall. Declining water levels with subsequent drying up of wells in the smaller valleys and upland draws can be expected during extended periods of below-normal rainfall. In addition because of the relatively shallow depth to water in the alluvium, transpiration by deep-rooted plants during the growing season often results in a decline of water levels.

RECORDS OF WELLS

Information pertaining to wells is given in Table 6. Measured depths of wells are given to the nearest tenth of a foot; reported depths are given in feet. Measured depths to water are given to the nearest hundredth of a foot; reported depths are given in feet. The well-numbering system used in Table 6 is described on page 7 and illustrated in Figure 2.

* Chemical analysis given in Table 3.
† Type of well: *Dr*, drilled; *Du*, dug; *B*, bored; *J*, jetted.
‡ Type of casing: *GI*, galvanized iron; *OB*, oil barrel; *S*, steel; *R*, rock; *C*, concrete; *OW*, oil-well casing; *P*, pipe; *B*, brick.
§ Method of lift: *Cy*, cylinder; *W*, wind; *N*, none; *G*, gasoline engine; *E*, electric motor; *H*, hand; *T*, turbine; *P*, propane engine; *T*, tractor; *J*, jet; *D*, diesel; *C*, centrifugal.
‖ Use: *S*, stock; *N*, none; *D*, domestic; *I*, irrigation; *O*, observation; *P*, public.

LOGS OF TEST HOLES AND WELLS

Listed on the following pages are logs of 176 test holes and wells. Logs designated "sample logs" describe test holes from which samples were collected. The logs are numbered according to the well-numbering system illustrated in Figure 2. Locations of wells and test holes are shown on Plate 1. Plate 2 illustrates the character of material penetrated by the test holes. Water-level measurements are stated in feet below land surface.

10-24-34ddd.———Sample log of test hole in SE SE SE sec. 34, T 10 S, R 24 W, 50 feet west and 20 feet north of center of crossroads, Graham County (Prescott, 1955, p. 92); drilled September 1952. Altitude of land surface 2,357.2 feet; depth to water 35.4 feet.

	Thickness, feet	*Depth, feet*
NEOGENE		
Pleistocene		
Peoria and Loveland formations		
Silt and clay, dark-brown	4	4
Silt, tan; contains some gastropod shells	15.5	19.5
Pliocene		
Ogallala Formation		
Clay, sandy, tan-brown	3.5	23
Sand, gravel, and pebbles	2	25
Clay, sandy, tan; contains imbedded gravel	9	34
Sand, fine to coarse	6	40
Sand, fine to coarse; contains some gravel and pebbles	5.5	45.5
CRETACEOUS		
Upper Cretaceous		
Niobrara Chalk—Smoky Hill Chalk Member		
Chalk, soft, white	2.5	48
Shale, gray	2	50

10-25-36ccc.———Sample log of test hole in SW SW SW sec. 36, T 10 S, R 25 W, 20 feet east and 15 feet north of center of crossroads, Graham County (Prescott, 1955, p. 92); drilled September 1952. Altitude of land surface 2,418.8 feet; depth to water 31.5 feet.

	Thickness, feet	*Depth, feet*
NEOGENE		
Pleistocene		
Peoria and Loveland formations		
Silt and clay, dark-brown (topsoil)	3	3
Silt and clay, tan-gray	6.5	9.5
Silt and clay, compact, tan; contains some sand near base	6.5	16
Pliocene		
Ogallala Formation		
Sand, fine to coarse and fine to coarse gravel; contains silt, sandy clay, and fragments of chalk	11	27
Clay, very sandy; contains gravel	5	32
Sand, fine to coarse, and fine to coarse gravel; contains some fragments of chalk	4.5	36.5
CRETACEOUS		
Upper Cretaceous		
Niobrara Chalk—Smoky Hill Chalk Member		
Chalk, soft, yellow	1.5	38
Shale, calcareous, gray	2	40

11-21-3ccc.———Sample log of test hole in SW SW SW sec. 3, T 11 S, R 21 W, 50 feet NE of SW cor. sec. 3; drilled October 1957. Altitude of land surface 2,094.5 feet; depth to water 9.61 feet.

	Thickness, feet	*Depth, feet*
NEOGENE		
Pleistocene		
Alluvium		
Silt, sandy, dark-brown	4	4
Sand, fine to coarse; contains chalk gravel	3	7
Silt, brown	1	8
Sand, fine to coarse, silty, and arkosic gravel; contains small amount chalk gravel	6	14
CRETACEOUS		
Upper Cretaceous		
Niobrara Chalk—Fort Hays Limestone Member		
Shale, chalky, white	5	19
Shale, dark-gray	1	20

11-21-9ada.———Sample log of test hole in NE SE NE sec. 9, T 11 S, R 21 W, 0.3 mile south of NE cor. sec. 9, at edge of road; drilled October 1957. Altitude of land surface 2,101.1 feet.

	Thickness, feet	*Depth, feet*
NEOGENE		
Pleistocene		
Grand Island, Sappa, and Crete formations, undifferentiated (terrace deposits)		
Silt, sandy, tan	4	4
Sand, fine to coarse; contains chalk gravel	17	21
CRETACEOUS		
Upper Cretaceous		
Niobrara Chalk—Fort Hays Limestone Member		
Shale, chalky, white	5	26
Shale, dark-gray	2	28

11-21-9add.———Sample log of test hole in SE SE NE sec. 9, T 11 S, R 21 W, 0.4 mile south of NE cor. sec. 9, at edge of road; drilled October 1957. Altitude of land surface 2,099.8 feet; depth to water 19.88 feet.

	Thickness, feet	*Depth, feet*
NEOGENE		
Pleistocene		
Grand Island, Sappa, and Crete formations, undifferentiated (terrace deposits)		
Silt, dark-brown	4	4
Silt, tan	5	9
Sand, fine to coarse; contains arkosic and chalk gravel	8	17
Silt, blue-gray	2	19
Sand, fine to coarse; contains chalk gravel	8	27
Silt, blue-gray	13	40
Silt, sandy, gray; contains small amount chalk gravel	10	50
Sand, fine to coarse, very silty; contains small amount chalk gravel	10	60
Silt, very sandy, dark-gray	3	63
Sand, fine to coarse, and chalk gravel	7	70
CRETACEOUS		
Upper Cretaceous		
Niobrara Chalk—Fort Hays Limestone Member		
Shale, gray	3	73

11-21-22ccc.———Sample log of test hole in SW SW SW sec. 22, T 11 S, R 21 W, 10 feet north and 10 feet east of SW cor. sec. 22; drilled September 1960. Altitude of land surface 2,309.5 feet.

	Thickness, feet	Depth, feet
NEOGENE		
Pleistocene		
Peoria and Loveland formations		
Silt, sandy, brown	5	5
Sand, fine to very coarse	7	12

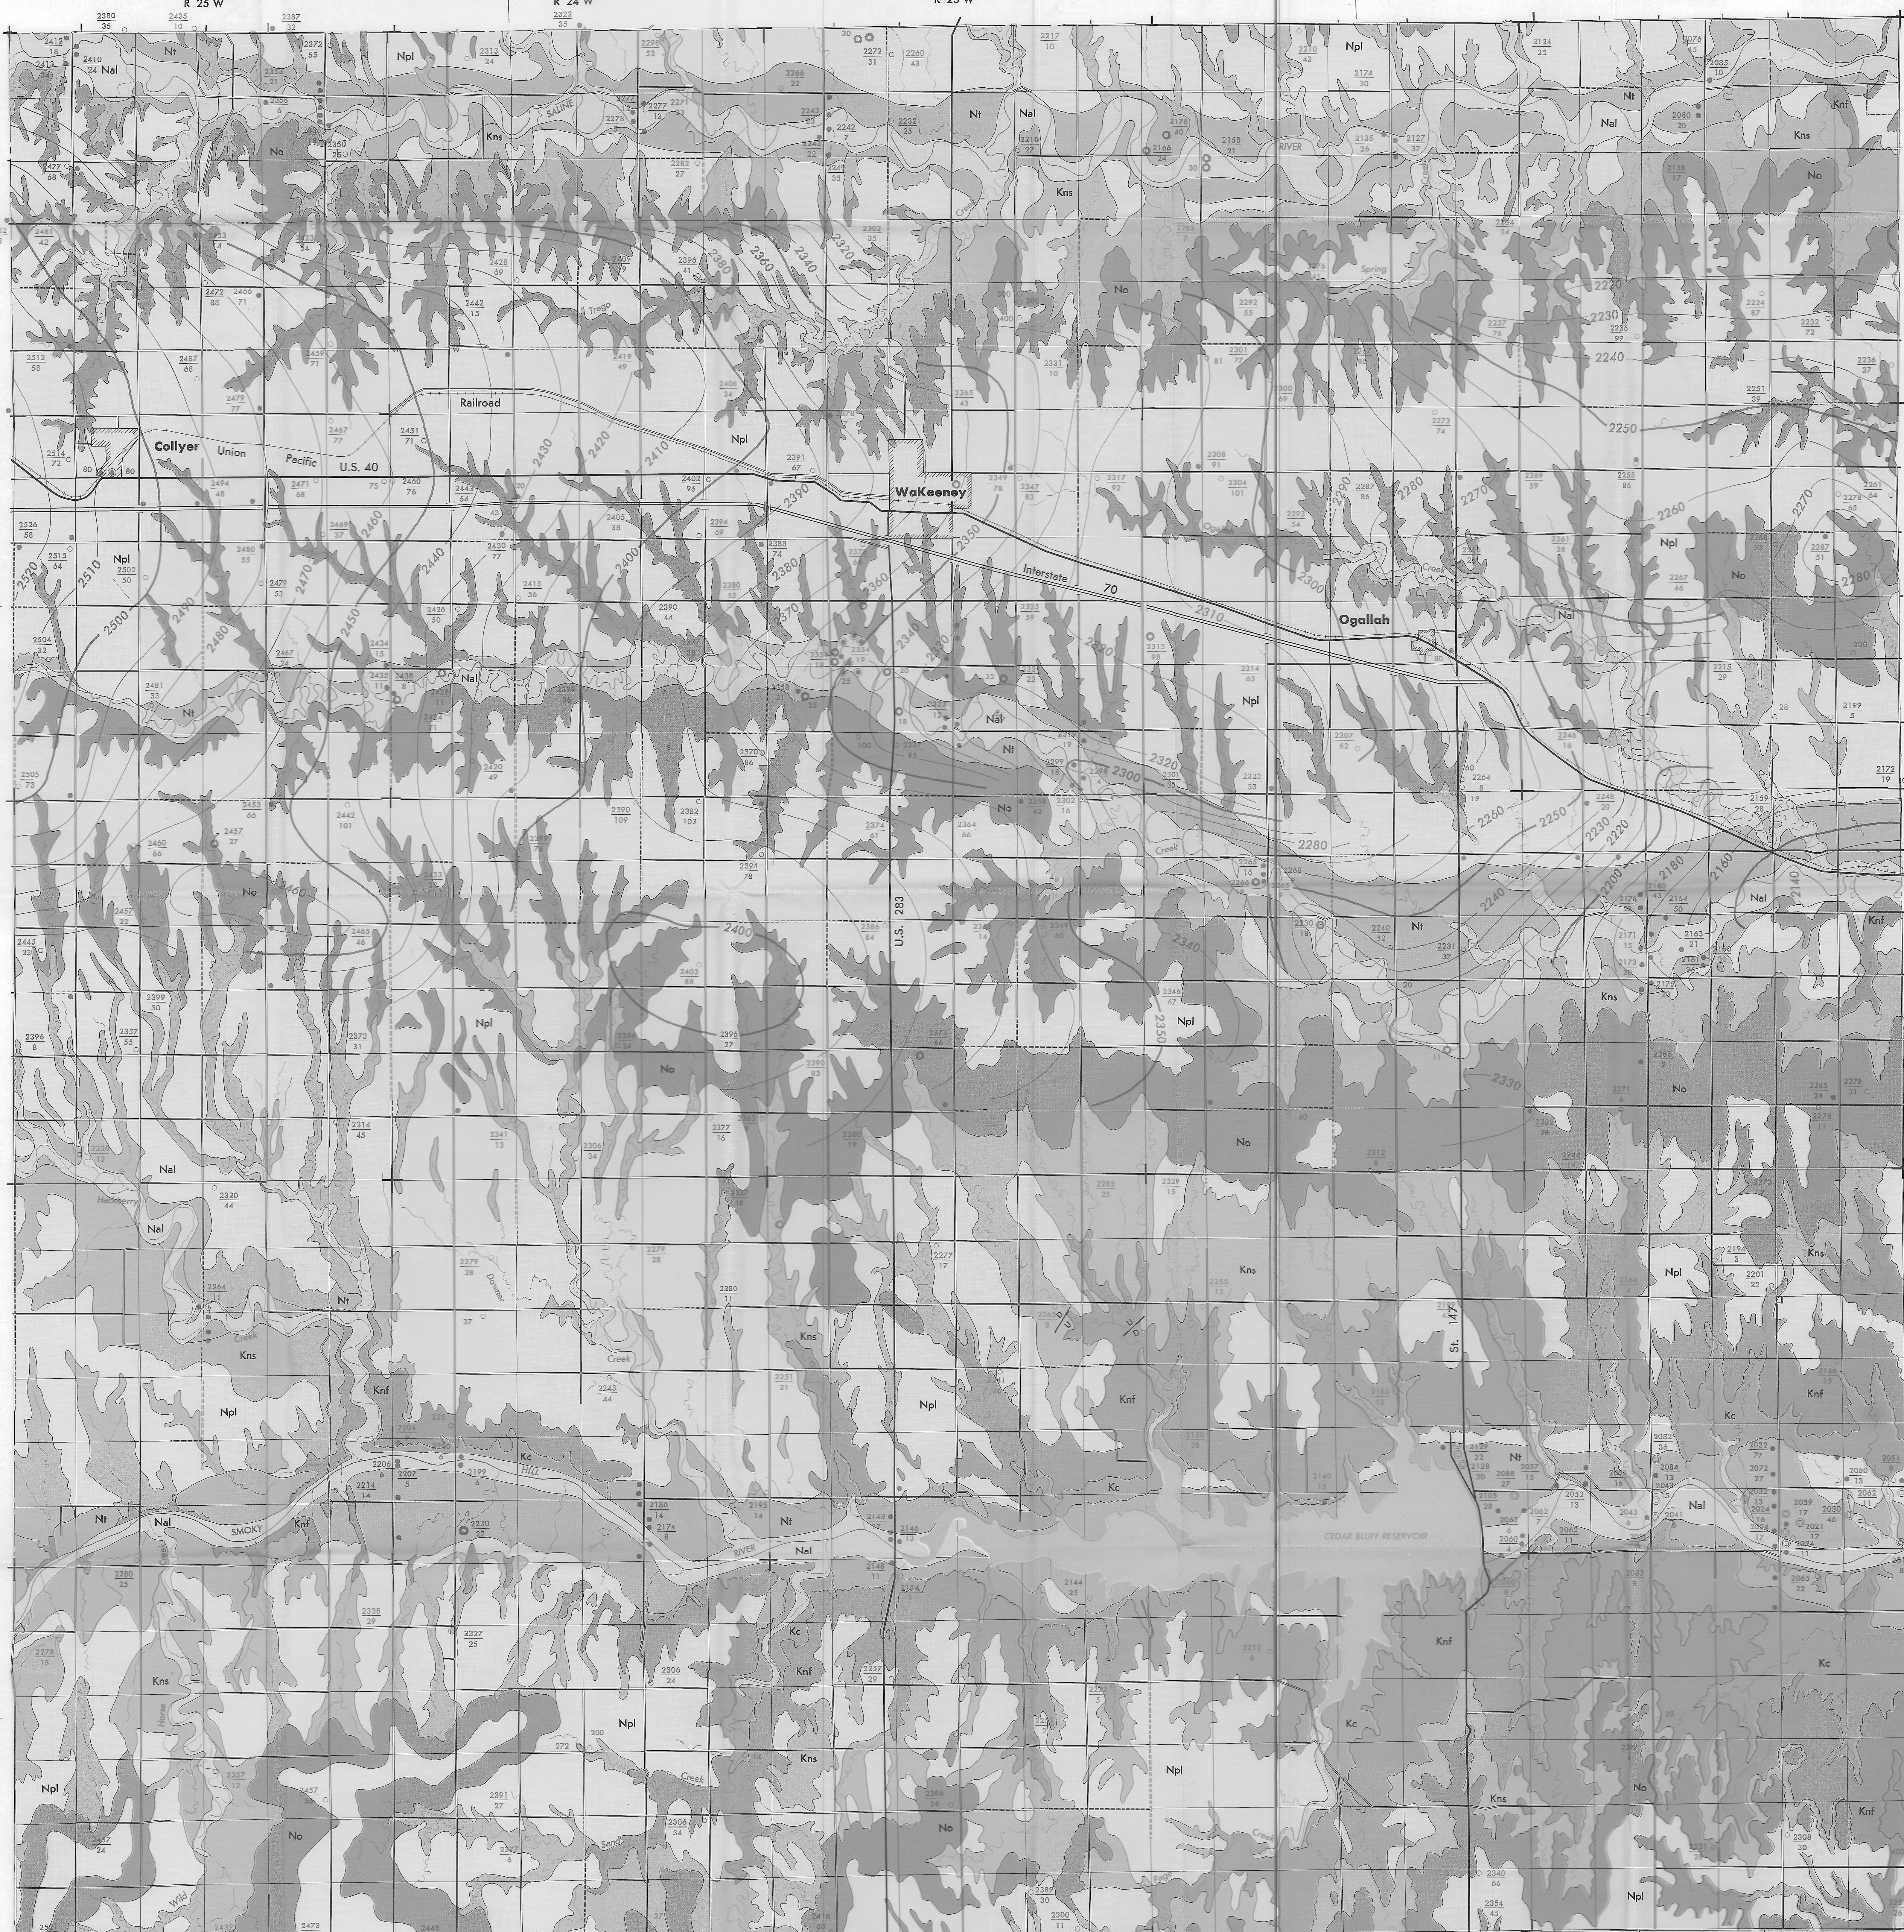
MAP OF TREGO COUNTY, KANSAS

showing areal geology, water-table contours, and location of wells and test holes for which records are given

By Warren G. Hodson

1965



Base and drainage compiled from maps prepared by the Soil Conservation Service

Areal geology mapped by Warren G. Hodson in 1959

EXPLANATION

NEOGENE

Pleistocene

Nal

Alluvium

Stream-laid deposits ranging in composition from clay to coarse sand and gravel. Occurs along principal stream valleys. Yields moderate to moderately large quantities of water to wells along larger valleys, lesser amounts along smaller valleys.

Npl

Peoria and Loveland Formations, undifferentiated

Silt, mostly eolian; sandy in lower part. Mantles most of the uplands and masks much of the valley walls. Includes slope wash derived from the Ogallala Formation along the edge of the uplands. Yields small quantities of water to wells locally.

Nt

Grand Island, Sappa, and Crete Formations (Terrace deposits).

Stream-deposited sand, gravel, and silt in a terrace position along the major valleys. Mostly continuous, but locally consists of remnants. Yields moderate quantities of water to wells.

Pliocene

No

Ogallala Formation

Consists chiefly of sand, gravel, silt, and clay, generally very calcareous. Mostly unconsolidated, but cemented at places to various degrees. Occurs in the uplands, chiefly in the northern and central parts of the county. Yields moderate quantities of water to wells.

CRETACEOUS

Upper Cretaceous

Niobrara Chalk

Kns

Smoky Hill Chalk Member

Chalk and chalky shale, thin-bedded and platy; bentonite beds occur throughout. Light gray to dark gray when fresh; weathers to brown and orange at outcrop. Yields no water to wells.

Knf

Fort Hays Limestone Member

Massive beds of chalk, separated by thin partings of chalky shale. Generally grayish-white, but may be yellow or light brown at outcrop. Yields small amounts of water to wells locally.

Kc

Carlile Shale

Lower part consists of calcareous shale and thin beds of chalky limestone; upper part consists of dark-gray clayey shale with lenses of silty, fine-grained sandstone near top. Yields small quantities of water to wells from Codell Sandstone Member at top of the formation.

2430

Contour connecting points of equal altitude of water table, based on instrumental levels (omitted where water table is discontinuous). Contour interval 10 feet.

2515
65

Upper number, altitude of water table above mean sea level, in feet; lower number, depth to water below land surface, in feet. (Single set of numbers indicates depth to water).
