## Geology and Ground-Water Resources of Decatur County, Kansas

Physical Belences Library
University of California

MAY 18 1972

#### ABSTRACT

Decatur County is a 900-square-mile area in the High Plains section of northwestern Kansas. The altitude of land surface ranges from about 2,330 to 2,970 feet above mean sea level. The climate is subhumid to semi-arid, with a mean annual precipitation of 18.42 inches.

The oldest rocks exposed consist of chalk and shale beds of Late Cretaceous age. The Cretaceous rocks crop out in only two small exposures but form the relatively impervious bedrock above which ground water occurs in nearly all the county. The Ogallala Formation of Tertiary (Pliocene) age overlies the Cretaceous rocks in the upland areas and is the most widespread aquifer in the county. Stream erosion has removed the Ogallala Formation along the principal valleys, but streams, through several cycles of alluviation, have subsequently deposited the more permeable sediments in the valleys. Eolian silts of late Pleistocene age mantle much of the upland areas and obscure the stream terraces along the principal valleys.

There are two principal aquifers in the county—the Ogallala Formation that underlies the upland areas and the relatively narrow alluvial deposits in the four major stream valleys. The upland areas have more areal extent than the alluvial valleys, but the highest yielding wells are in the major valleys where most of the irrigation is practiced. Based on population figures and livestock statistics, an estimated 750 to 1,000 acre-feet of ground water is used annually in rural areas for household and livestock purposes. Three cities use a total of about 400 acre-feet of ground water per year. About 17,000 acre-feet of ground water is appropriated for the irrigation of 10,500 acres. Ground water in the county is moderately hard, but its quality is adequate for most purposes.

#### INTRODUCTION

#### Scope of Investigation

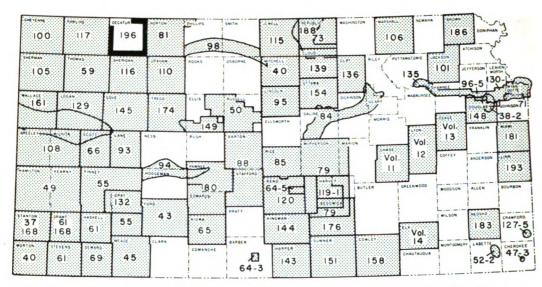

This report of a study of the ground-water resources of Decatur County, Kans., was made as part of the ground-water program of the State Geological Survey of Kansas and the United States Geological Survey, in cooperation with the Division of Water Resources of the Kansas State Board of Agriculture and the Environmental Health Services of the Kansas State Department of Health. The status of the program and the location of Decatur County are shown on figure 1.

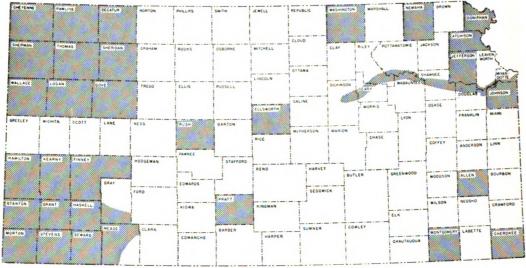

A test-drilling program was started in northwestern Kansas in 1952. Data obtained from this program are included in this report. About 3 months during the summer and fall of 1962 were spent in the field by the author gathering additional data on which this report is based. The areal geology was mapped from field observations and from stereoscopic study of aerial photographs obtained from the U.S. Department of Agriculture. Data on the 355 water wells inventoried as a part of this project are given in table 6. Logs of 35 wells and test holes are given at the end of the report. Aquifer tests made in the alluvial deposits in the principal valleys were used to compute the coefficients of transmissibility. Samples of water collected from representative wells were analyzed under the supervision of Howard A. Stoltenberg, Chemist, in the Sanitary Engineering Laboratory of the Kansas State Department of Health.

#### **Previous Investigations**

Studies related to the geology or to the ground-water resources of Decatur County and adjacent areas have been made by several people. Adams (1898) has given a historical summary of the early studies of the Cretaceous rocks Williston (1897) discussed the in Kansas. Pleistocene deposits of Kansas. Haworth contributed reports on the physiography (1897a), Tertiary deposits (1897b), and ground water (1897c) in western Kansas. Studies of the High Plains and their ground-water resources were made by Johnson (1901, 1902) and Darton (1905). In a special report on well waters in Kansas, Haworth (1913) discussed the waterbearing characteristics of deposits in western Kansas. Elias (1937) reported on the geology of Decatur and Rawlins Counties with special reference to water resources. A report by Byrne and others (1950) describes the occurrence of construction materials in Decatur County. Frye and Leonard (1952) discussed the Pleistocene

Report published or in print (number).

Investigation in progress.

This report

FIGURE 1.—Index maps of Kansas showing area discussed in this report and other areas for which ground-water reports have been published by the State Geological Survey or are in preparation.

geology of Kansas; and Frye, Leonard, and Swineford (1956) discussed the Ogallala Formation of northern Kansas. Ground-water studies in counties that border Decatur County were made by Frye (1945), Frye and Leonard (1949), Prescott (1955), Bayne (1956), and Walters (1956).

#### Well-Numbering System

The locations of wells and test holes in this report are designated according to General Land

Office surveys in the following order: township, range, section, quarter section, quarter-quarter section, and quarter-quarter section (10-acre tract). The quarter sections, quarter-quarter sections, and 10-acre tracts are designated a, b, c, and d in a counterclockwise direction beginning in the northeast quadrant. For example, well 1-30W-35cdd is in the SE½ SE½ SW½ sec. 35, T. 1 S., R. 30 W. (fig. 2). If more than one well or test hole is located in the same 10-acre tract, the location numbers are

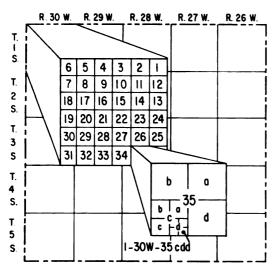

FIGURE 2.—Well-numbering system used in this report.

followed by serial numbers in the order in which they were inventoried.

#### Topography and Drainage

Decatur County, an area of about 900 square miles, is in the High Plains section of the Great Plains physiographic province (Frye and Schoewe, 1953). Gently rolling uplands moderately dissected by small drainageways comprise much of the county. Four principal streams (Beaver Creek, Sappa Creek, Prairie Dog Creek, and North Fork Solomon River) cross the county in a northeasterly direction. The slopes into the valleys of the principal streams tend to be gentle, but they are steeper and more rugged in most places along the south side of Beaver Creek valley in the northwestern part of the county. The general slope of the land surface of Decatur County is eastward. The total topographic relief is about 640 feet. The lowest altitude of land surface, about 2,330 feet above mean sea level, is in the channel of Sappa Creek at the Decatur County-Norton County line; the highest altitude, about 2,970 feet above mean sea level, is in the uplands in the southwestern part of the county between Sappa Creek and Prairie Dog Creek.

#### Climate

Decatur County has a subhumid to semiarid climate characterized by slight to moderate precipitation, moderately high average wind velocity, and rapid evaporation. The mean annual precipitation at Oberlin is 18.42 inches, and the mean annual temperature is 53.2°F

TABLE 1.—Monthly and annual precipitation and temperature at Oberlin, 1931-60 (from records of U.S. Weather Bureau).

(table 1). The average length of the growing season is 160 days. The average date of the last killing frost is May 2, and the average date of the first killing frost is October 9. About 70 percent of the precipitation occurs during the growing season. Rainfall is erratic, however, sometimes coming as storms of 3 inches or more; at other times, several weeks may pass without an appreciable amount of precipitation.

According to the U.S. Census in 1960, Decatur County had a population of 5,778, an average of 6.4 persons per square mile as compared to a State average of 26.6 persons. Oberlin, the county seat, had a population of 2,337. Other cities and their 1960 populations are: Norcatur, 302; Jennings, 292; and Dresden, 134.

#### GEOLOGIC SETTING

#### Summary of Stratigraphy<sup>1</sup>

#### SUBSURFACE ROCKS

The subsurface rocks in Decatur County do not yield potable water to wells. However, a brief summary of their occurrence is presented because of their significance to the occurrence of oil in northwestern Kansas.

Structural setting.—Decatur County is located on the northwestern flank of the Cambridge arch, the principal structural element in northwestern Kansas. This uplift of granitic, gneissic, and schistose basement rocks, which are about 3,800 feet below land surface, is reflected nearly to the surface through that thickness of sedimentary rocks of Palcozoic and Mesozoic ages (Merriam and Hambleton, 1956;

<sup>&</sup>lt;sup>1</sup> The classification and nomenclature of rock units used in this report are those of the State Geological Survey of Kansis and differ somewhat from those of the U.S. Geological Survey.

Merriam, 1963; Scott and McElroy, 1964). The Precambrian arched surface plunges southeastward and slopes both northeastward and southwestward. The Jennings anticline on the west side of the arch in Decatur County is a subsidiary structure that plunges southward (Merriam, 1963).

Paleozoic rocks.—Rocks of Pennsylvanian and Permian age, which overlie Precambrian rocks in much of Decatur County, are known from oil-well borings. Rocks of Mississippian age thin on the flanks of the Cambridge arch and are absent over the crest. Older Paleozoic rocks are upturned, truncated, and overstepped on the flanks. The Paleozoic rocks are about 1,700 feet thick and yield some oil to wells in Decatur County.

Mesozoic rocks.—In addition to the thick rocks of Late Cretaceous age that crop out sparsely in Decatur County (discussed below), other Mesozoic rocks of Jurassic and Early Cretaceous age underlie the county. The thickness of all the Mesozoic rocks ranges from about 1,600 to about 2,200 feet (Merriam, 1963).

Oil production from subsurface rocks.— Through 1965 about 5,500,000 barrels of oil had been produced from 14 small oil fields having from 1 to 18 wells each. Oil production has been from Pennsylvanian rocks from 109 wells ranging in depth from 3,156 to 3,863 feet. No oil has yet been produced from rocks of other ages, but exploration continues in the county (Beene and Oros, 1967).

#### **OUTCROPPING ROCKS**

The areal distribution of rocks exposed in Decatur County is shown on plate 1. The rocks are sedimentary in origin and range in age from Cretaceous to Recent. A generalized section of the rock units and their water-bearing properties is given in table 2. The stratigraphic relation of the rock units is illustrated by geologic sections on plate 2.

The oldest rocks that crop out in Decatur County are chalk and shale beds of Late Cretaceous age. Two small outcrops of Cretaceous rocks were noted in Decatur County by the author; elsewhere, Cretaceous rocks are overlain by younger deposits. The Cretaceous rocks are relatively impervious and retard or prevent the downward percolation of water, thereby serving as an impervious floor below the overlying permeable fluviatile deposits. The rocks underlying the Cretaceous chalk and shale beds are not known to contain potable water in northwestern Kansas.

The Ogallala Formation of Tertiary age (Pliocene Series) unconformably overlies the Cretaceous rocks in the upland areas of Decatur County. Erosion during the Pleistocene Epoch has removed it along the valleys of the larger streams, but elsewhere in the county, the Ogallala Formation is present. Owing to its widespread occurrence and generally porous texture, the Ogallala is an important source of ground water.

Unconsolidated deposits of both fluviatile and eolian origin represent the Pleistocene Series in Decatur County. Fluviatile deposits occur along the principal streams and are shown on plate 1 as alluvium (Wisconsinan and Recent age) and as the Crete Formation (Illinoisan age). The Crete Formation underlies the terraces along the larger stream valleys. Eolian deposits (Loveland Formation of Illinoisan age and the Peoria Formation of Wisconsinan age) mantle the uplands and valley slopes and in places overlie the terrace deposits along the stream valleys.

#### Geologic Formations

#### CRETACEOUS SYSTEM— UPPER CRETACEOUS SERIES

#### NIOBRARA CHALK

The Niobrara Chalk of Late Cretaceous age is the oldest rock formation that crops out in Decatur County. Only one small outcrop of the Niobrara was noted in Decatur Countyalong the road and ditches about 0.4 mile east of the SW1/4 cor. sec. 12, T. 1 S., R. 26 W., on the north side of Sappa Creek valley near the northeastern corner of the county. The total thickness of the Niobrara Chalk in Decatur County is about 600 feet, but only a small part of the formation is exposed. The outcropping rock consists chiefly of brown and orange-brown silicified chalk beds separated by thin chalky shale partings. The Niobrara is relatively impervious and is not known to yield water to wells in Decatur County.

#### PIERRE SHALE

The Pierre Shale of Late Cretaceous age conformably overlies the Niobrara Chalk. A small outcrop of the Pierre Shale occurs in the southwestern part of the county along the north side of South Fork Sappa Creek valley in secs. 2 and 3, T. 4 S., R. 30 W. Because it is relatively soft and easily eroded, the Pierre Shale does not crop out as good exposures. However, it is locally near the surface under the slopes

Generated at University of Kansas on 2023-10-04 21:21 GMT / https://hdl.handle.net/2027/ucl.31210014409245 Public Domain in the United States, Google-digitized / http://www.hathitrust.org/access\_use#pd-us-google

water to wells along major valleys, and JESSET amounts along smaller valleys. of the larger valleys, particularly along Beaver Creek valley and along North Fork Sappa Creek valley in the western part of the county. The Pierre Shale consists of dark-gray thin-bedded clayey shale, commonly with limonite stains along fractures. Selenite crystals characterize weathered exposures. It ranges in thickness from a thin edge in the central part of the county to about 600 feet in the northwestern part. It is relatively impervious and is not known to yield water to wells in Decatur County.

#### TERTIARY SYSTEM— PLIOCENE SERIES

#### OGALLALA FORMATION

The Ogallala Formation of Pliocene age is divided into three members in Kansas which are, in ascending order, the Valentine, Ash Hollow, and Kimball. No attempt was made to divide the Ogallala Formation in Decatur County, and it is treated as a single unit in this report.

Character.—The Ogallala Formation was deposited on an erosional surface of Upper Cretaceous rocks by eastward-trending streams whose source of sediment was igneous rocks of the Rocky Mountains and sedimentary rocks of eastern Colorado. During early stages of deposition of the Ogallala, through-flowing streams which headed in the Rockies occupied broad, shallow valleys across what now constitutes the High Plains. As deposition continued, valleys became filled, divides were covered, topographic relief was reduced, and the depositional zones of individual streams overlapped and coalesced. Thus, the Ogallala Formation consists of a heterogeneous complex of predominantly clastic deposits, ranging in texture from clay to very coarse gravels and pebbles. The lithology changes abruptly both vertically and laterally, and only rarely can an individual bed be traced for any appreciable distance. Although the sediments are largely unconsolidated, cementation of beds occurs to some extent. Calcium carbonate is a common constituent, both as interstitial material and as stringers and nodules of caliche. Silica also is present as a cementing material in beds of opaline sandstone or as chert.

Sand is the principal material within the Ogallala and is present at all horizons. Although beds of uniform grain size occur, the sand in most beds ranges from fine to coarse and commonly is mixed with gravel, silt, or clay. Beds of silt, sandy silt, and clayey silt are

present throughout the Ogallala and are mostly pink, tan, gray, and greenish gray. Where the fine sediments contain a large amount of calcium carbonate, they are light gray or white.

The topographic expression of the formation includes flat uplands, gentle erosional slopes, and nearly vertical cliffs. Typical outcrops are cemented to various degrees and are ash gray in color. Because the cemented beds are more resistant to erosion, hard ledges and knobby, irregular benches are characteristic.

Distribution and thickness.—The Ogallala Formation occurs extensively in Decatur County, overlying the Cretaceous rocks in most of the county. Erosion during the Pleistocene Epoch has removed the Ogallala along the principal valleys, but elsewhere in the county, although generally mantled with eolian silts, the Ogallala underlies the uplands and valley slopes and serves as the principal aquifer from which domestic and stock supplies are obtained.

The Ogallala Formation rests on a subacrially eroded surface developed on chalk and shale beds of Late Cretaceous age. This surface has a relief of several hundred feet in Decatur County and slopes generally eastward at about 10 to 15 feet per mile. Logs of test holes show that the thickness of the Ogallala in Decatur County ranges from a thin edge along the outer margins of the stream valleys to more than 200 feet in the interstream areas.

#### QUATERNARY SYSTEM— PLEISTOCENE SERIES

Deposits of Pleistocene age, although relatively thin, are the surficial deposits in much of Decatur County. They include the Crete Formation of Illinoisan age (terrace deposits), the Loveland Formation of Illinoisan age and the Peoria Formation of Wisconsinan age (loess deposits), and alluvium of late Wisconsinan and Recent age.

The classification of Pleistocene deposits by the State Geological Survey of Kansas is based on the classification of glacial deposits in the midcontinent region (Frye and Leonard, 1952; Bayne and O'Connor, 1968). Correlations between the glaciated and nonglaciated areas have been made on the basis of continuous loesses, molluscan fauna, buried soils, and petrologically distinctive volcanic ash (Condra and others, 1947; Frye and others, 1948).

#### CRETE FORMATION

Character.—Deposits classified as the Crete Formation in this report occur along the major valleys as older alluvial deposits in a position

topographically higher than the modern flood plain. The deposits consist chiefly of sand, gravel, and silt that were deposited by streams during earlier aggradational cycles. Only the upper part of the deposits is exposed in the county, and the deposits have not been dated on the basis of fossils. That the deposits are largely the Crete Formation of Illinoisan age is indicated by their topographic position above the modern flood plain, the relative youthfulness of the terrace, and the lithologic and stratigraphic similarity to deposits that are classified as Illinoisan in age in adjacent and nearby areas. It is possible that fluviatile deposits of Kansan age occur in places in the basal part of the deposits as they do locally in central and northcentral Kansas, but the terrace is believed to be Illinoisan in age. Loess deposits blanket and obscure the terrace locally. Where loess is present, the terrace deposits appear to grade into the Loveland Formation, further indicating an Illinoisan age for the terrace deposits.

The upper part of the terrace deposits is composed of tan or gray silt that is similar in many respects to the upland loess. The soil profile generally is well developed, and at places there are one or more buried soil zones. Columnar structure is common, and shells of fossil gastropods are found locally. In general, the deposits are coarser at depth, and sandy silt, sand, and gravel are found in the basal part.

Distribution and thickness.—The Crete Formation occurs as terrace deposits along the major valleys in the county. The deposits are much more common along the north sides of the valleys than along the south sides. Along the north side of Beaver Creek valley in the northwestern part of the county and along the north side of the North Fork Solomon River valley in the southeastern corner, the Crete is exposed nearly continuously. The Crete occurs along much of Sappa Creek valley northeastward from the city of Oberlin. However, much of the Crete Formation has been removed by stream erosion, and in places only remnants remain. The width of the terrace is generally from a quarter to half a mile. Loess and slope wash have obscured the deposits to the extent that it is difficult to delineate the outer edge of the terrace.

The Crete Formation ranges in thickness from a thin edge along the margins of the deposits to more than 60 feet in test hole 1-26W-8ddd. Along the principal valleys it is generally from 50 to 60 feet thick. In general, the thickness increases eastward across the county.

#### LOVELAND AND PEORIA FORMATIONS

Character.—The Loveland Formation is a reddish-tan silt, mostly eolian, which commonly grades into sandy silt or sand in the lower part. The buried Sangamon Soil marks the top of the Loveland and separates it from the overlying Peoria Formation. The Peoria is a tan to gray massive eolian silt that blankets much of the upland areas. The deposits classified as Loveland and Peoria in this report are above the water table and yield no water to wells.

Distribution and thickness.—Loess of late Pleistocene age covers a considerable part of Decatur County with a relatively thin mantle ranging in thickness from a thin edge to as much as 52 feet in test hole 1-31W-laaa. In general, the thickness of the loess is greater in the northwestern part of the county. The loess caps the rolling hills and flat uplands and tends to mask the valley slopes and subdue the topography. Although the Sangamon Soil occurs between the Loveland Formation of Illinoisan age and the Peoria Formation of Wisconsinan age, the formations could not be readily separated, and are mapped as one unit on plate 1.

#### ALLUVIUM

Character.—Alluvium of late Wisconsinan and Recent age occurs as relatively narrow deposits beneath the flood plains of the principal streams in the county. The alluvium consists of the deposits beneath the narrow stream channels and the adjacent low terraces commonly inundated by flood waters. The deposits, largely silt and sand, become coarser with depth. Beds of very coarse sand and gravel are common in the middle and lower parts of the alluvium. The upper part consists predominantly of silt and sandy silt deposited during floods.

Distribution and thickness.—The width and thickness of the alluvium are greatest in the principal valleys. Along Beaver Creek and Sappa Creek valleys, the alluvium ranges from about half a mile to a mile in width; along Prairie Dog Creek and South Fork Solomon River valleys, the alluvium ranges from about half to three-quarters of a mile in width. It ranges in thickness from a thin edge along the margins of the deposits to as much as 90 feet in irrigation well 1-27W-34bab. In the principal valleys the alluvium is generally about 50 to 70 feet thick in the deepest parts of the valley fill.

#### **GROUND WATER**

#### Source and Occurrence

Ground water in Decatur County is derived almost entirely from precipitation within the county or nearby. Part of the precipitation returns to the air by evaporation, part moves away as surface runoff into streams, and part infiltrates into the ground. A very small part percolates downward through the soil and underlying strata until it reaches the water table becomes ground-water recharge. ground water moves slowly to points of discharge in directions determined largely by the shape and slope of the water table. Ground water is discharged by springs or wells, by seeps into streams, or by evaporation or transpiration near the land surface, commonly along stream valleys. The movement of ground water in Decatur County is generally eastward, and some ground water leaves the county by subsurface outflow.

#### Water Table and Movement of Ground Water

The configuration of the water table in Decatur County is shown on plate 1 by water-table contours that connect points of equal altitude of the water level. The water-table contours were compiled from measurements of depth to water in wells and test holes, the surface altitudes of which were determined by plane table and alidade. Water-level measurements and altitudes of land surface for the wells are given in table 6 and for the test holes are given at the end of this report. Ground water moves downgradient at right angles to the contours.

The water table has a generally eastward gradient of 10 to 15 feet per mile. Along the four principal valleys, however, the contours swing sharply upstream, indicating that ground water is moving from the Ogallala Formation toward the stream valleys and into the alluvial deposits. In some localities near the principal valleys, the water table has a gradient of about 50 feet per mile toward the stream valleys. Considerable discharge occurs by evaporation and transpiration along the valley sides where the contact of the Ogallala Formation and the underlying Cretaceous bedrock is near the land surface.

#### Recharge

#### LOCAL PRECIPITATION

The mean annual precipitation in Decatur County is about 18 inches, but only a small

fraction of the precipitation reaches the water table and becomes ground water. The slope of the land surface and the type of material through which the water must percolate are important factors that affect the amount and frequency of recharge. The broad, flat alluvial surfaces of the principal valleys offer excellent conditions for recharge. The alluvial deposits contain sand, silt, and sandy silt, and the water table is near the land surface; consequently, the infiltration of water generally is relatively rapid. Conversely, in the maturely dissected uplands, the land surface is characterized by waterways and moderately steep slopes underlain by massive beds of silt and buried soils, and the water table lies at a considerable depth. These areas receive relatively little recharge, probably less than half an inch per year.

#### STREAMS AND PONDS

The four principal streams that flow across Decatur County are entrenched below the water table and receive water from the ground-water reservoir. Thus, they do not constitute sources of recharge, except in local areas where heavy pumping from wells near major streams may have lowered the water table temporarily below the level of the stream channel. The smaller tributary streams are above the water table, and during periods of stream runoff following rain or melting snow, some water seeps into the underlying deposits to supplement the ground water. Surface ponds also constitute a source of recharge where the ponds are above the water table and are underlain by permeable materials.

### INFILTRATION OF IRRIGATION WATER

Recharge from water applied for irrigation can amount to 25 or 30 percent of the applied water where good recharge conditions exist. In Decatur County, most of the irrigated land is in the principal valleys where the alluvial deposits consist chiefly of silt, sand, and sandy silt, and where the soil is relatively permeable. Thus, conditions in the valleys are conducive to the return of irrigation water to the groundwater reservoir. Although there were 83 irrigation wells in the county at the time of this investigation in 1962, only a small part of the land was under irrigation. Because irrigation is not extensive and because the areal extent of the alluvial valleys is relatively small, the amount of recharge to the aquifer from the return of irrigation water is not considered significant. However, the return of irrigation

water to the ground-water reservoir represents a source of recharge, and as irrigation becomes more extensive, an increasing amount of recharge will occur. Only a few irrigation wells have been drilled in the uplands of Decatur County; thus, the recharge from irrigation water applied in the uplands is negligible.

#### Discharge

#### NATURAL

Before any wells were drilled in Decatur County, the ground-water reservoir was in approximate equilibrium—that is, the average annual recharge plus subsurface inflow of ground water to the county was equal to the average annual discharge plus the outflow of ground water from the county. The factors producing discharge by ground-water movement into the principal stream channels and by evaporation and transpiration by plants in low-lying areas of shallow water table have changed little, and loss by these means still accounts for the major part of the ground-water discharge from the county.

#### **WELLS**

Municipal water departments reported a use of about 400 acre-feet of ground water in 1961. According to records of the Division of Water Resources of the Kansas State Board of Agriculture, 17,000 acre-feet of ground water per year was appropriated for irrigation as of October 1963. About 3,900 acre-feet of ground water was reported used for irrigation in 1962 by 60 irrigation wells, with more than 20 irrigators not reporting. An estimated annual use of 6,000 to 8,000 acre-feet of ground water is used for irrigation in Decatur County.

Most rural residents obtain water for domestic and livestock purposes from small-diameter drilled wells equipped with cylinder pumps, many of which are powered by windmills. The yields of these wells are small and probably average about 1 gpm (gallon per minute). Because of their considerable number and long pumping periods, however, such wells represent an important withdrawal of ground water, which is estimated to be 750 to 1,000 acre-feet per year for household and livestock purposes.

#### Inflow and Outflow

As indicated by the water-table contours on plate 1, the movement of ground water in the interstream areas is in an easterly direction. Hence, a small amount of recharge from pre-

cipitation that occurs in eastern Rawlins County moves into western Decatur County. Computations using the saturated thickness of water-bearing deposits along geologic section A-A' (pl. 2) near the western edge of the county, the water-table gradient (pl. 1), and an assumed average coefficient of permeability of 300 gpd (gallons per day) per square foot indicate a subsurface inflow of about 5,000 acre-feet per year. The saturated thickness along section B-B' in the eastern part of the county is about equal to the saturated thickness along section A-A'. Assuming equal permeability, the subsurface outflow from Decatur County probably is equal to the subsurface inflow.

#### Water in Storage

To determine the quantity of ground water in storage in the Pliocene and Pleistocene deposits, a map showing the saturated thickness of the deposits (fig. 3) was prepared by superimposing a contour map of the water table upon a contour map of the bedrock surface (fig. 4) and connecting points of equal saturated thickness. The area between contours was measured with a planimeter and was multiplied by the average saturated thickness to give the volume of saturated materials. Assuming a specific yield (ratio of the volume of water the saturated part of the aquifer will yield, by gravity, to its own volume) of 20 percent from the saturated materials, about 5 million acre-feet of ground water would be available for pumping from the Pliocene and Pleistocene deposits if the deposits were completely drained. From a practical standpoint, much less water than this would be available for pumping.

## Hydrologic Properties of Water-Bearing Materials

## COEFFICIENTS OF STORAGE AND TRANSMISSIBILITY

The quantity of ground water that an aquifer will yield to wells depends upon the hydrologic properties of the material forming the aquifer. The hydrologic properties of greatest significance are the ability of the aquifer to store and transmit water, which are measured by the coefficients of storage and transmissibility, respectively. Aquifer tests provide the data to compute these coefficients.

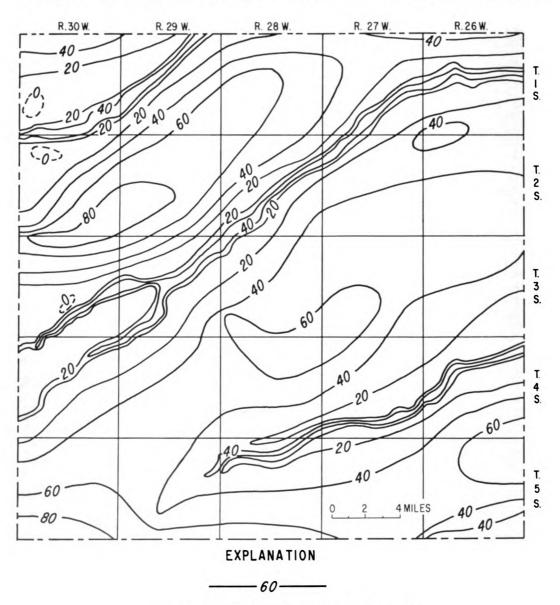

The coefficient of storage (S) may be expressed as the change in the stored volume of water per unit surface area of the aquiter per unit change in the component of head normal to that surface.

The coefficient of transmissibility (T) may be expressed as the rate of flow of water, in gallons per day, through a vertical strip 1 foot wide and extending the full height of the saturated thickness of the aquifer, under a hydraulic gradient of 1 foot per foot, at the prevailing ground-water temperature.

The field coefficient of permeability (P) can be computed by dividing the coefficient of transmissibility by the aquifer thickness (m), and may be expressed as the rate of flow of water, in gallons per day, through a cross-sectional area of 1 square foot, under a hydraulic gradient of 1 foot per foot, at the prevailing ground-water temperature.

Aquifer tests were made in three of the principal valleys. An existing irrigation well and two observation wells constructed at ap-

/ https://hdl.handle.net/2027/ucl.31210014409245 Generated at University of Kansas on  $2023-10-04\ 21:21\ GMT$  Public Domain in the United States, Google-digitized / h propriate distances from the pumped well were used for each aquifer test.

Figure 5 shows the results of the tests using drawdown measurements in the observation wells and analysis by the Thiem method. The coefficients of transmissibility also were computed by the Theis nonequilibrium method and by the Jacob modified nonequilibrium method.

The results obtained by these methods were similar to those obtained by the Thiem method shown on figure 5. The theory of these methods and its application are discussed by Ferris and others (1962). The results of the aquifer-test analyses indicated coefficients of transmissibility of 70,000 gpd per foot near well 5-28W-5dcd1 in Prairie Dog Creek valley, 120,000 gpd per

foot near well 3-29W-21bad1 in Sappa Creek valley, and 100,000 gpd per foot near well 1-29W-30bdd1 in Beaver Creek valley.

The aquifer tests indicate the hydrologic properties only in the vicinity of the test, but they are believed to be indicative of the hydrologic properties that can be expected for much of the alluvial deposits along the principal valleys in the county.

## DRAWDOWN, DISTANCE, AND TIME RELATIONSHIPS

To compute possible future drawdowns in the vicinity of any particular well, assumptions were made that all water pumped would be from storage within the aquifer, that pumping would be continuous at a rate of 1,000 gpm, and that the water-bearing material has a T of 100,000 gpd per foot and an S of 0.2. The computations of drawdown are in error to the extent that these assumptions are in error, but the computations are probably of the right order of magnitude.

Figure 6 shows, under the assumed conditions specified, the drawdown of water level at any distance from the pumped well after 1, 10,

100, and 1,000 days. After 10 days of pumping at a rate of 1,000 gpm, the drawdown 10 feet from the well would be 11 feet, the drawdown 100 feet from the well would be 5.8 feet, and the drawdown 1,000 feet from the well would be nearly 1 foot. After 100 days of pumping, the drawdown 100 feet from the well would be 8.4 feet.

Figure 7 shows the rate of decline caused by pumping under the assumed conditions. The decline of water level 100 feet from a well pumped at 1,000 gpm would be 5.8 feet after 10 days, and 8.4 feet after 100 days.

The cone of depression caused by a pumping well will increase in area and depth in response to pumping. Large-yielding wells can interfere with one another unless the wells are spaced at considerable distances. When wells mutually interfere, the drawdown at any one point will be the sum of the drawdowns produced by each well at that point. When wells interfere, the pumping lift in each well is increased and the discharge is decreased. To maintain a constant discharge would further increase the drawdown and extend the cone of depression. In areas where many wells are pumping from the same aquifer, the large cone of depression resulting

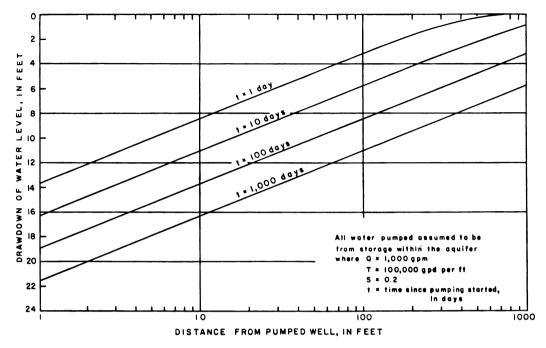

FIGURE 6.—Drawdown of water level at any distance from the pumped well after pumping has begun.

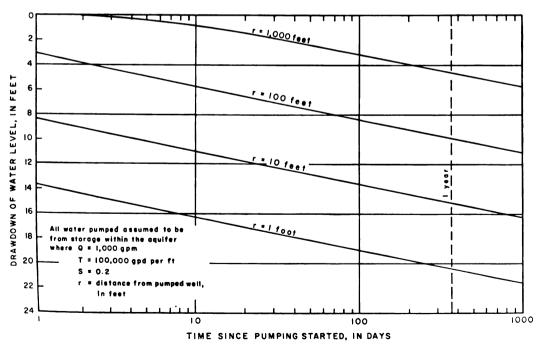

FIGURE 7.—Drawdown of water level at any time after pumping has begun.

from mutual interference may not have sufficient time to recover between pumping periods, and the water level may decline persistently.

As shown by the water-table contours on plate 1, ground water in the Ogallala Formation along the edges of the upland areas is moving toward the stream valleys. Because the water table is near the land surface along the valley edges and because of the slow movement of the water, a large part of this water either is evaporated or is transpired by plants. However, if sufficient ground water were pumped from the valley aquifers to appreciably increase the gradient of the water table along the edges of the valleys, it is possible that part of the ground water now lost to evaporation and transpiration in the shallow-water areas along the edges of the valleys could be induced into the deeper part of the valley aquifers, and thus eventually become available for pumping by wells. In addition, increased pumping from a valley aquifer could lower the water level sufficiently to intercept some water that now discharges into streams.

Most of the land irrigated with ground water in Decatur County is in the alluvial valleys, and about half of the land irrigated is in Sappa Creek valley, which extends northeastward across the central and northern parts of the county. If it is assumed that the alluvial deposits within Sappa Valley have an average width of half a mile, a length of 30 miles, an average saturated thickness of 30 feet, and a specific yield of 20 percent, then about 60,000 acre-feet of water is in storage in the alluvial deposits of Sappa Creek valley. Obviously, it would be impossible to pump all this water from the aquifer. However, the amount of water in storage in Sappa Valley, as computed above, is nearly 4 times the amount of ground water appropriated (17,000 acre-feet) in all Decatur County in 1962, and is more than 15 times as much as the ground water pumped for irrigation (3,900 acre-feet) in Decatur County in 1962, as reported by the Division of Water Resources of the Kansas State Board of Agriculture.

#### Availability

The people of Decatur County are fortunate that potable ground water is available at most places in the county. In some areas, the quantity is sufficient only for domestic and stock supplies. In other areas, yields of several hundred to more than 1,000 gpm are available from wells and, therefore, are sufficient for irrigation or industrial use.

There are two principal aquifers in Decatur County—the alluvial deposits in the stream valleys and the Ogallala Formation that underlies the upland areas. The quantity of water that is available from the aquifers is dependent upon the saturated thickness and the permeability of the deposits. Although the upland areas have considerably more areal extent than the alluvial valleys, the highest-yielding wells are in the major valleys, and it is here that most of the irrigation is practiced. The higher yields are due to the higher permeabilities of the valley deposits.

Depth to water level in the valleys generally ranges from about 10 to 40 feet below land surface. Depth to water level in the uplands exceeds 100 feet below land surface in most places and is 200 feet or more below land surface in some of the topographically higher parts of the county.

#### **ALLUVIAL VALLEYS**

The relatively narrow alluvial deposits along the principal stream valleys are an important source of ground water. The alluvial deposits are shown on the geologic map (pl. 1) as alluvium and the Crete Formation. The alluvium underlies the modern flood plain. The Crete Formation underlies the terrace along the outer margins of the valleys, the terrace ranging in most places from 10 to 25 feet higher than the flood plain. The alluvium of Wisconsinan and Recent age and the fluvial deposits of the Crete Formation are lithologically similar and are in contact with each other. The water table in the alluvial valleys is continuous in both the alluvium and the Crete Formation.

Many domestic and stock wells obtain water from the valley deposits, and most irrigation wells in the county are in the stream valleys. Small to large quantities of ground water are available from the valley deposits at most localities in the principal valleys. In areas of greater saturated thickness, ground water in quantities adequate for irrigation can be obtained. Yields of irrigation wells along Beaver Creek and Sappa Creek valleys range from about 500 gpm to a reported 1,450 gpm, and yields from irrigation wells along Prairie Dog Creek and the North Fork Solomon River valleys range from about 300 to 700 gpm.

#### **OGALLALA FORMATION**

The uplands of Decatur County are mantled by deposits of silt, sand, and gravel of the Ogallala Formation, which are as much as 240

feet thick and average about 200 feet thick in most of the upland areas. The saturated thickness of the deposits exceeds 80 feet in places and averages about 45 feet (fig. 3). The Ogallala Formation is the most widespread water-bearing formation in the county. It supplies water for most domestic and stock purposes and for several irrigation wells. Yields of wells in the Ogallala range from a few gallons per minute from domestic and stock wells to a reported 825 gpm from irrigation well 5-30W-35bcb.

Only a few irrigation wells had been drilled in the uplands of Decatur County at the time of this field investigation, although wells in areas of greater saturated thickness may be expected to yield as much as 500 gpm.

#### Utilization

Data on 355 wells are given in table 6. Only part of the domestic and stock wells were visited, but records were made of all municipal and irrigation wells in the county at the time of this investigation. The principal uses of ground water in the county are given below.

#### DOMESTIC AND STOCK SUPPLIES

One of the chief uses of ground water in Decatur County is for domestic and stock purposes. Quantities of ground water adequate for domestic and stock needs are available at nearly all places in the county. Most domestic and stock wells are drilled wells equipped with displacement-type pumps. Most pumps are operated by windmills; others are operated by electric or gasoline motors, or by hand.

#### MUNICIPAL SUPPLIES

Data regarding city wells and details of well construction are given in table 6. Data collected at the time of this field investigation regarding municipal water supplies are given below. Dresden (1960 population of 134) had no municipal water supply.

#### OBERLIN

Oberlin obtains its water supply from six drilled wells in the alluvial deposits of Sappa Creek valley near the southern and southeastern edges of the city. Each well yields about 300 gpm and is equipped with an electrically driven turbine pump. The elevated storage tank has a capacity of 500,000 gallons. Water used in 1961 was about 112 million gallons, as reported by the city water department.

#### Norcatur

Norcatur obtains its water supply from three drilled wells in the Ogallala Formation near the northwestern edge of the city. Two of the wells are equipped with electrically driven turbine pumps; the other well is equipped with a dieseldriven centrifugal pump. Storage is provided by an elevated storage tank with a capacity of 50,000 gallons. Water used in 1961 was about 10 million gallons, as reported by the city water department.

#### JENNINGS

Jennings obtains its water supply from one drilled well in the alluvial deposits of Prairie Dog Creek valley near the northwestern edge of the city. The well is equipped with an electrically driven turbine pump with a capacity of 200 gpm. Storage is provided by an elevated storage tank with a capacity of 45,000 gallons. Water used in 1961 was about 7 million gallons, as reported by the city water department.

#### IRRIGATION SUPPLIES

There were 83 irrigation wells in Decatur County in the fall of 1962, all but 10 of which were in the alluvial valleys. Beaver Creek valley, which extends across the northwestern corner of the county, had the greatest concentration of irrigation wells and also the highest-yielding wells in general. In this valley, a number of irrigation wells have yields exceeding 1,000 gpm, and nearly all have yields exceeding 500 gpm.

Sappa Creek valley had the greatest number of irrigation wells (nearly half) because of its greater length in transversing the county. Yields of several hundred gallons per minute may be obtained from wells in Sappa Creek valley and a few irrigation wells have yields of about 1,000 gpm.

Several irrigation wells were in Prairie Dog Valley. Although most yields were less than those in Beaver Valley or Sappa Valley, the irrigation wells in Prairie Dog Valley yield about 300 to 500 gpm.

The North Fork Solomon Valley extends across the southeastern corner of Decatur County. The length of the valley in the county is about 6 miles, and several irrigation wells were in this part of the valley. The yield of most of these wells ranged from about 300 to 700 gpm.

At the time of this investigation, only 10 irrigation wells were in the uplands deriving water from the Ogallala Formation. Reported

yields of irrigation wells in the uplands ranged from 55 to 825 gpm.

According to records of the Division of Water Resources of the Kansas State Board of Agriculture, 17,000 acre-feet of ground water was appropriated for the irrigation of 10,500 acres as of October 1963. Irrigators reported that about 3,900 acre-feet of ground water from 60 irrigation wells was applied in 1962 to about 3,000 acres, with more than 20 irrigators not reporting.

#### Chemical Quality

The chemical character of ground water in Decatur County is indicated by analyses of samples from wells deriving water from the principal aquifers (table 3). The results of the analyses are given in parts per million. The analyses show only the dissolved mineral constituents and do not indicate the sanitary condition of the water.

### CHEMICAL CONSTITUENTS IN RELATION TO USE

Ground water in Decatur County is predominantly a calcium bicarbonate type. The water is moderately hard, with most of the hardness resulting from the presence of calcium and magnesium (carbonate hardness). The characteristics and concentrations of the principal chemical constituents are given in table 4. Most samples of water contained less than 500 ppm (parts per million) dissolved solids, and only one sample contained more than 1,000 ppm. The samples were low in nitrate and chloride content. Only one sample exceeded 250 ppm sulfate. The iron content was fairly high in many samples.

Ground water in the alluvial valleys is somewhat more mineralized than ground water in the Ogallala Formation. The sulfate content was appreciably higher in the alluvial valleys, particularly along Sappa Creek and Beaver Creek valleys.

#### SANITARY CONSIDERATIONS

The analyses of water in table 3 give only the dissolved-solids content and do not indicate the sanitary quality of the water. Water containing mineral matter that imparts an objectionable taste or odor may be free from harmful bacteria and safe for drinking. Conversely, water clear and pleasant to the taste may contain harmful bacteria. Great care should be taken to protect domestic and public water supplies from pollution. To guard against con-

tamination, a well must be properly sealed to keep out dust, insects, vermin, debris, and surface water. Wells should not be placed where barnyards, privies, or cesspools are possible sources of pollution.

## SUITABILITY OF WATER FOR IRRIGATION

Sodium is required in very limited amounts for most plant growth. However, sodium in high concentrations is not only toxic to plants but also detrimental to the soil, particularly where leaching is not adequate. It has been widely recommended that the percentage of sodium (equivalents per million of sodium divided by total equivalents per million of sodium, potassium, calcium, and magnesium) should not exceed 50 or 60 percent. In 1954, the staff of the U.S. Salinity Laboratory proposed that the sodium hazard of irrigation water could best be expressed in terms of the sodium-adsorption ratio, or SAR. This ratio expresses the relative activity of sodium ions in exchange reactions with soil. The effect of sodium in irrigation water is discussed in detail in U.S. Department of Agriculture Handbook 60 (U.S. Salinity Laboratory Staff, 1954), which was used as a guide for the following discussion of the relation of sodium to irrigation water.

Deterioration of soil that was originally nonsaline and nonalkaline may result if an excess of soluble salts or exchangeable sodium is allowed to accumulate as a result of inadequate leaching and drainage of the soil. If the amount of water applied to the soil is not more than is needed by plants, water will not percolate downward below the root zone, and mineral matter will accumulate. Likewise, impermeable soil zones near the surface can retard the downward movement of water and cause waterlogging of the soil and deposition of salts.

Analyses of water samples from 10 irrigation wells deriving water from the principal aquifers in Decatur County were used to illustrate the suitability of ground water for irrigation (table 5).

Sodium-adsorption ratios and electrical conductivities are plotted on figure 8 to provide a classification of waters for irrigation use. Low-sodium water (S1) can be used for irrigation on most soils with little danger of development of harmful levels of exchangeable sodium. Medium-sodium water (S2) may be used safely on coarse-textured or organic soils having good permeability, but S2 water will present an ap-

1 Samples analyzed by H. A. Stoltenberg, Kansas State Department of Health.

In a same where the nitrate content of water is known to exceed 45 ppm, the public should be warned of the potential dangers of using the water for infant feeding (U.S. Public Health Service, 1962, p. 7).

TABLE 4.—Quality of water in relation to use.

| Principal constituents     | Characteristics   | Acceptable maximum concentration, in parts per million <sup>1</sup> | Range in<br>concentration,<br>in parts per million |
|----------------------------|---|---|--|
| Dissolved solids           | Water high in dissolved solids may have a disagreeable taste or a laxative effect. When water is evaporated, the residue consists mainly of the minerals listed in table 3.   |   | 250-1,147  |
| Hardness                   | Hardness is caused by calcium and magnesium. Forms scale<br>in vessels used in heating or evaporative processes. Hardness<br>is commonly noticed by its effect when soap is used with<br>the water. Carbonate hardness can be removed by boiling,<br>noncarbonate hardness cannot.          | <b>;</b><br>i   | 166-626  |
| Iron (Fe)                  | Stains cooking utensils, plumbing fixtures, and laundry.<br>Water may have a disagreeable taste.  | 0.3   | 0-2.2  |
| Fluoride (F)               | Fluoride concentration of about 1 ppm in drinking water used by children during the period of calcification of teeth prevents or lessens the incidence of tooth decay; 1.5 ppm may cause mottling of the tooth enamel (Dean, 1936). Bone changes may occur with concentrations of 8-20 ppm. |   | 0.1-1.1  |
| Nitrate (NO <sub>2</sub> ) | Nitrate concentration of 90 ppm may cause cyanosis in infants (Metzler and Stoltenberg, 1950). Comly (1945) states that concentrations of 45 ppm may be harmful to infants. Adverse effects from drinking high-nitrate water are also possible in older children and adults.                |   | 0.4-19   |
| Sulfate (SO <sub>4</sub> ) | Derived from solution of gypsum and oxidation of iron sulfides (pyrite, etc.). Concentrations of magnesium sulfate (Epsom salt) and sodium sulfate (Glauber's salt) may have a laxative effect on some persons.   |   | 5.3-282  |
| Chloride (Cl)              | Chloride in ground water may be derived from connate marine water in sediments, surface contamination, or solution of minerals containing chlorides.  |   | 9-133  |

<sup>&</sup>lt;sup>1</sup> Concentrations as recommended by the U.S. Public Health Service (1962).

TABLE 5.—Suitability for irrigation of ground water from selected wells.

| Well<br>number | Sample<br>number on<br>figure 8 | Na<br>(equivalents<br>per million) | Ca + Mg<br>(equivalents<br>per million) | SAR  | Conductivity<br>(micromhos per<br>centimeter at 25°C) |

preciable sodium hazard in certain fine-textured soils, especially under poor-leaching conditions. With increasing sodium hazard, harmful levels of exchangeable sodium will result in most soils unless special soil management is practiced, such as good drainage, leaching, and additions of organic matter.

Low-salinity water (C1) can be used for irrigation on most soils with little likelihood that soil salinity will develop. Medium-salinity water (C2) can be used if a moderate amount of leaching occurs. With increasing salinity, less exchangeable sodium can be tolerated and more leaching will be required to prevent salinity damage. On figure 8, all the waters were classified as low-sodium water (S1) and either medium-salinity water (C2) or high-salinity water (C3).

#### RECORDS OF WELLS AND TEST HOLES

Information pertaining to wells and test holes is given in table 6. The wells and test holes are listed in order by townships from north to south, and by ranges from east to west. Within a township, they are listed in order of the section numbers. The well-numbering system is illustrated on figure 2. Measured depths of wells and depths to water level are given in feet and tenths. Reported depths of wells and depths to water level are given to the nearest foot.

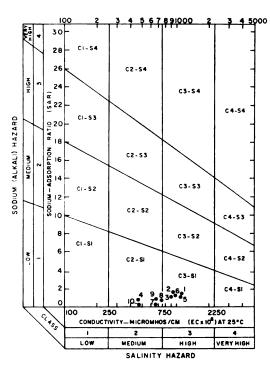

FIGURE 8.—Classification of water used for irrigation (method of the U.S. Salinity Laboratory Staff, 1954). Number by circle refers to table 5.

#### LOGS OF WELLS AND TEST HOLES

Listed on the following pages are logs of 35 selected wells and test holes. Logs of an additional 56 wells and test holes used in the preparation of this report are retained in the files of the U.S. and State Geological Surveys, Lawrence, Kans., and may be consulted there.

The logs are numbered according to the well-numbering system illustrated on figure 2. Location of wells and test holes are shown on plate 1. The character of the material drilled is illustrated on plate 2. Logs designated "sample log" describe test holes which were drilled by the State Geological Survey of Kansas and from which samples were collected. Water-level measurements are given in feet below land surface.

1-26W-5bbb.—Sample log of test hole in the NW¼ NW¼ NW¼ sec. 5, T. 1 S., R. 26 W., 14 feet east and 12 feet south of center of crossroads; drilled October 12 feet south of center of and 1952. Altitude of land surface, 2,531 feet.
